Pasteur showed that inoculations with preparations of attenuated (weakened) pathogens could be used to develop immunity against the virulent (infectious) form of the pathogen. However, not until 20th-century advances in immunology—for example, Burnet's clonal selection theory in 1957 and the discovery of T cells and B cells in 1965—did scientists gain a modern understanding of vaccines. Effective vaccination stimulates the body to launch an immune response against the antigens contained in the vaccine. Memory cells develop, and future encounters with the same pathogen are dealt with rapidly.

Microbiologists prepare effective vaccines in various ways. They can attenuate a pathogen so that it loses its ability to cause disease. When pathogens are cultured for long periods in nonhuman cells, mutations adapt the pathogens to the nonhuman host so that they no longer cause disease in humans. This method is used to produce the Sabin polio, measles, mumps, and rubella vaccines. Tetanus and diphtheria vaccines are made from toxins secreted by the respective pathogens. The toxin is altered so that it can no longer destroy tissues, but its antigenic determinants are still intact.

Researchers are developing **DNA vaccines** (or RNA vaccines) consisting of plasmids that have been genetically engineered to produce specific antigens from a pathogen. When injected into a patient, the altered DNA is taken up by cells and makes its way to the nucleus. The encoded antigens are manufactured and stimulate both cell-mediated and antibody-mediated immunity. Numerous DNA vaccines, including vaccines to prevent and treat HIV infection, are in clinical trials. Researchers are also developing DNA vaccines that could provide immunity to multiple pathogens with a single injection.

Passive immunity is borrowed immunity When individuals have been exposed to certain diseases such as measles or hepatitis A, physicians may inject them with gamma globulin containing antibodies to the pathogen. The individuals injected develop **passive immunity**, boosting the body's defenses against

the disease. However, gamma globulin injections offer protection for only a few weeks. Because the body has not actively launched an immune response, it has no memory cells and cannot produce antibodies to the pathogen. Once the injected antibodies are broken down, the immunity disappears.

Pregnant women confer naturally induced passive immunity on their developing babies by manufacturing antibodies for them. These maternal antibodies, of the IgG class, pass through the placenta and provide the fetus and newborn infant with a defense system until its own immune system matures. Babies who are breast-fed continue to receive immunoglobulins, particularly IgA, in their milk during the critical months when their own immune system is developing.

Remember that passive immunity is borrowed immunity. Its effects are temporary, whether the immunity is artificially or naturally induced (see Table 45-1).

CHECKPOINT 45.5

- List the sequence of events that occur in antibody-mediated immunity.
- VISUALIZE** Draw an antigen–antibody complex. Describe three ways that antigen–antibody complexes affect pathogens.
- What is the basis of immunological memory?
- How is passive immunity different from active immunity?

45.6 Response to Disease, Immune Failures, and Harmful Reactions

LEARNING OBJECTIVES

- Describe the body's response to cancer cells and HIV.
- Describe examples of hypersensitivity, including autoimmune diseases, Rh incompatibility, and allergic reactions, and summarize the immunological basis of graft rejection.

The immune system is generally very effective in defending the body against invading pathogens. However, many

factors can impair immune function, including genetic mutations, malnutrition, sleep deprivation, pre-existing disease, stress, and virulent pathogens. Ineffective or inappropriately directed immune responses can also result in disease states.

Exaggerated, damaging immune responses are referred to as *hypersensitivity*. For example, sometimes the immune system malfunctions and attacks its own tissues, causing *autoimmune disease*. In allergic reactions, individuals are over-responsive to mild environmental antigens. The immune system's ability to distinguish self from nonself sometimes interferes with clinical interventions. Physicians must carefully consider immune system responses when employing such life-saving procedures as blood transfusions or organ transplants.

Cancer cells evade the immune system

Cancer is a leading cause of death worldwide and the second-leading cause of death in Western countries. An estimated one person in three in the United States will develop cancer, and one in five will die of cancer. Worldwide, lung cancer in men and breast cancer in women are the main types of cancer resulting in death. In our earlier discussions of cancer in Chapters 17 and 39, we explained that cancer is actually a complex group of diseases characterized by dysregulation of normal control mechanisms for cellular growth. Here we focus on the interaction between cancer cells and cells of the immune system and on new treatment strategies based on immune mechanisms.

Cancer cells are body cells that have been transformed in a way that alters their normal growth-regulating mechanisms. Every day a few normal cells may be transformed into precancer cells in each of us in response to the sun's UV rays, X-rays, certain viruses, tobacco smoke, asbestos, and other chemical carcinogens in the environment as well as other unknown factors.

Figure 45-13 A cytotoxic T cell destroying a cancer cell
This color-enhanced SEM shows a cytotoxic T_C cell (orange) attacking a cancer cell (pink). When a T_C cell attaches to a cancer cell, it releases compounds that induce the cancer cell to undergo apoptosis (programmed cell death).

How does the immune system respond? And why are immune responses sometimes ineffective?

Cancer cell antigens are classified according to their molecular structure and their source. Some cancer cell antigens are produced by mutant genes that are associated with cancer cells. T cells may respond to them because these antigens are not found in normal cells. Other cancer cell antigens are normal proteins that may stimulate immune responses because they are expressed in abnormally large quantities.

The human papillomavirus (HPV), which has been linked to several types of cancer (including cervical cancer and head and neck cancer), produces antigens that stimulate T cells to respond. Adaptive immune responses sometimes prevent the development of such DNA virus-induced cancers.

Cancer cell antigens induce both cell-mediated and antibody-mediated immunity NK cells and macrophages destroy cancer cells. Macrophages produce cytokines, including TNFs that inhibit tumor growth. Dendritic cells present antigens to T cells, stimulating them to produce interferons, which have an antitumor effect. T_C cells attack cancer cells directly and also produce interleukins, which attract and activate macrophages and NK cells (FIG. 45-13). Although the immune system recognizes many cancer cell antigens, these antigens often stimulate only weak immune responses that are not effective.

Sometimes cancer cells evade the immune system and multiply unchecked. Some types of cancer cells can block T_C cells. Others dramatically decrease their expression of class I MHC molecules. Recall that T_C cells recognize only antigens associated with class I MHC, so a low level of these molecules prevents tumor destruction. Some cancer cells do not produce co-stimulatory molecules needed to activate T_C cells.

Future cancer treatment will be more targeted Cancer treatments, such as chemotherapy and radiation, are designed to kill cells that are rapidly dividing. However, these treatments destroy normal cells as well as cancer cells. To treat cancer effectively, treatment strategies must be more specific, or even customized to the particular cancer. For example, cancer researchers are genetically engineering cancer cells to secrete cytokines that would stimulate the patient's immune response.

A few cancer drugs, such as Herceptin, are monoclonal antibodies. Herceptin binds with a growth-factor receptor that is present in excessive numbers on the cells of about 30% of metastatic breast cancers. Herceptin blocks the growth factors that would stimulate proliferation of the cells.

The spread of cancer typically depends on the development of blood vessels that bring nutrients and oxygen to the tumor. *Angiogenesis inhibitors* slow the development of blood vessels and thereby slow the spread of cancer. Many studies under way are attempting to optimize the clinical benefits of these drugs.

Researchers are developing DNA vaccines made from bits of DNA from a patient's cancer cells. When injected into the patient, the vaccine stimulates increased production of the target antigens. In response, the patient's immune system launches cell-mediated responses to tumor-associated antigens. These vaccines differ from traditional vaccines that

are used to destroy pathogens *before* they cause disease. Effective new treatment protocols for cancer will use a systems approach and combinations of medications. Cellular mechanisms are complex, and when a drug blocks one signaling pathway, cancer cells often work around the blocked reaction or take advantage of a redundant pathway. When combinations of drugs are used, more than one signaling pathway, or different parts of the same pathway, can be targeted.

Gene therapy research is another rapidly expanding area of study that is targeting cancer and other immune diseases. A new gene can be added or a faulty gene replaced to strengthen the body's defenses or cure cancer. Medical researchers are using CRISPR/Cas9 technology to change a human cell line to represent the disease genetically and functionally. Using recently developed research tools, cancer research is moving ahead rapidly and at lower cost.

Immunodeficiency disease can be acquired or inherited

The absence or failure of some component of the immune system can result in **immunodeficiency disease**, a condition that increases susceptibility to infection. Worldwide, the leading cause of *acquired* immunodeficiency in children is protein malnutrition. Lack of protein decreases T-cell numbers and decreases the ability to manufacture antibodies, which impairs the immune system. This condition increases the risk of contracting *opportunistic infections*, infections by microbes that do not typically cause disease. Another important cause of acquired immunodeficiency is chemotherapy administered to cancer patients because chemotherapy is most damaging to cells that divide rapidly, including blood stem cells and activated lymphocytes.

Inherited immunodeficiencies have an estimated incidence of 1 per 10,000 births. *Severe combined immunodeficiency syndromes (SCIDs)* are X-linked and autosomal recessive disorders that profoundly affect both cell-mediated immunity and antibody-mediated immunity, resulting in multiple infections. Babies born with SCID typically die by two years of age unless they are maintained in a protective bubble until they can be effectively treated, typically with bone marrow transplants.

In *DiGeorge syndrome*, the thymus is reduced or absent, and the patient is deficient in T cells. Children born with this disorder are prone to serious viral infections. Treatment involves transplanting bone marrow or fetal thymus tissue. Other tissues may take over T-cell production, and function typically improves by age five.

Researchers use several animal models to study immunodeficiency. For example, the nude mouse (a hairless mutant mouse) does not develop a functional thymus. Because nude mice are deficient in mature T cells, they are used to study the effects of compromised cell-mediated immunity as well as possible treatments. *Stem cell research* and advances in genetic engineering, including CRISPR/Cas9, suggest new approaches to treating immunodeficiency (see Chapters 16 and 17).

HIV is the major cause of acquired immunodeficiency in adults

The **human immunodeficiency virus (HIV)** was first isolated in 1983 and was shown to be the cause of **acquired immunodeficiency syndrome (AIDS)** in 1984. HIV, which is a retrovirus, has been studied more than any other virus. (Recall from Chapter 24 that a retrovirus is an RNA virus that uses its RNA as a template to make DNA with the help of reverse transcriptase.) Several different strains of the virus are known; HIV-1 is the most virulent form in humans (see Fig. 23-12).

The AIDS pandemic has claimed more than 35 million lives and has infected more than 78 million people since 1981. HIV kills approximately 1 million people every year. Epidemiologists estimate that more than 37 million people worldwide, including nearly 3 million children, are now infected with HIV. More than 2 million people are newly infected with HIV each year. Unfortunately, due to extreme poverty, less than half of the people diagnosed with AIDS receive antiretroviral therapy. The General Assembly of the United Nations has called AIDS a “global emergency” and has outlined measures for mobilizing world resources to combat this disease. HIV/AIDS is more than a medical issue; it is a political, economic, and human rights threat.

HIV is transmitted through body fluids from infected individuals, including semen, vaginal secretions, blood, and breast milk. Transmission occurs mainly during sexual intercourse with an infected person or by direct exposure to infected blood or blood products. Sharing needles and/or syringes (usually for drug injection) with an infected person is a major risk factor. The virus is not spread by casual contact. People do not contract HIV by hugging, casual kissing, sharing food or water, or using the same bathroom facilities. Friends and family members who have contact with AIDS patients are not more likely to become infected than those who do not have such contact.

In the United States, more than 39,000 new HIV infections occur each year. Of these new infections, almost 70% occur in men. Sexual contact with persons who have HIV infection is a risk factor that can be modified. Use of a latex condom during sexual intercourse provides some protection against HIV transmission, and use of a spermicide containing nonoxynol-9 may provide additional protection.

As many as one-third of untreated pregnant women infected with HIV will transmit the virus to their babies during pregnancy, childbirth, or breast-feeding. Recent drug treatment protocols have reduced the rate of HIV transmission between mother and fetus. Clinical studies are ongoing to confirm reports that beginning treatment (using triple antiretroviral drugs) of HIV-infected infants within the first 30 hours of life may lead to a cure after about 18 months.

In high-income countries, effective blood-screening procedures now safeguard blood bank supplies, markedly reducing the risk of infection by blood transfusion. In low- and middle-income countries, HIV continues to be a health threat, particularly to women and newborns. As treatment, prevention, and education programs are implemented, the incidence of new infections in many parts of the world is decreasing.

HIV destroys the host immune system HIV typically enters the body through the mucosa that lines passageways into the body. A protein on the outer envelope of the virus attaches to CD4 on the surface of T_H cells, the main target (FIG. 45-14). The virus also binds to a co-receptor that normally binds a chemokine. HIV enters the T_H cell and is reverse transcribed to form DNA. Its DNA is then incorporated into the host genome. The virus reproduces itself, causing death of the host cell. The first phase of HIV infection is the *acute* phase of the infection. Within two weeks of infection, large numbers of T_H and memory T cells are destroyed. HIV also infects dendritic cells and macrophages. Dendritic cells in the mucous membranes transport HIV from their point of entry to the lymph nodes. The virus further spreads through the blood.

The body launches an immune response following HIV infection. Innate responses include production of antimicrobial peptides and action by NK cells, dendritic cells, and the complement system. Adaptive immune responses include activation and mobilization of T_C cells.

An estimated 13% of HIV-infected individuals in the United States do not know that they are infected. During the first few weeks after infection, some people experience mild flulike symptoms (fever, headache, sore throat, aching muscles). However, some individuals have no symptoms.

The acute phase transitions into the latent period, a *chronic* phase, as the immune system decreases HIV in the blood. Some cells infected by HIV are not destroyed, and the virus may continue to replicate slowly for many years. T_C cells appear to be the main cells that attack HIV, limiting viral replication and delaying the progress of the disease. However, over time HIV continues to destroy T_H cells, resulting in a dramatic decrease in the T_H -cell population. This decrease severely impairs the

Figure 45-14 HIV infecting T helper cell (color-enhanced SEM) HIV (red particles) attack and destroy T_H cell (green). Depletion of T_H is the main reason for the failure of the immune system in HIV infection.

body's ability to resist infection because T_H cells are needed to release the cytokines that activate T_C cells and B cells. After a time, a progression of symptoms occurs, including swollen lymph glands, night sweats, fever, and weight loss (FIG. 45-15). Too often, the virus eventually wins the battle.

In most HIV-infected individuals, the disease eventually progresses to AIDS, the final, and often lethal, stage. This process can take more than ten years, and antiretroviral drugs

Figure 45-15 The course of HIV infection

Exposure to semen, blood, vaginal secretions, or breast milk containing HIV can lead to HIV infection. The acute (early) infection begins in lymph nodes and other lymph tissues associated with epithelial linings. Most T_H cells may be destroyed within two weeks of infection. During the latent period, chronic infection develops, and the virus replicates at a low level. Eventually, viral replication may increase and lead to a progression of symptoms and to AIDS. Although some exposed individuals apparently do not become infected, the risk increases with multiple exposures. Many factors determine whether a person exposed to HIV will develop AIDS.

slow the process. By the time the disease progresses to AIDS, lymph tissue has been destroyed and the blood T_H cell count has dropped below a critical level of 200 cells/ μ L. As a consequence of this immunosuppression, many AIDS patients develop serious opportunistic infections, such as tuberculosis, or cancers, such as lymphomas and Kaposi's sarcoma (a tumor of the endothelial cells lining blood vessels that causes purplish spots on the skin). In about one-third of AIDS patients, the virus infects the nervous system and causes *AIDS dementia complex*. These patients exhibit progressive cognitive, motor, and behavioral dysfunction that typically ends in coma and death.

Researchers are searching for effective treatments

Researchers throughout the world are searching for anti-retroviral drugs that will successfully combat the AIDS virus. Because HIV often infects the central nervous system, an effective drug must cross the blood–brain barrier. **Azidothymidine (AZT)**, the first anti-retroviral drug developed to treat HIV infection, can prolong the period prior to the onset of AIDS symptoms. AZT inhibits the action of reverse transcriptase, the enzyme the retrovirus uses to synthesize DNA. As a result, AZT blocks HIV replication. Without producing DNA, the virus cannot incorporate itself into the host cell's DNA. Unfortunately, the reverse transcriptase that HIV uses to synthesize DNA makes many mistakes: about 1 in every 2000 nucleotides it incorporates is incorrect. By mutating in this way, viral strains resistant to AZT have evolved.

Protease inhibitors block the viral enzyme protease, resulting in viral copies that cannot infect new cells. Protease inhibitors are used in combination with AZT and other reverse transcriptase inhibitors. Triple-combination treatment has been very effective for many AIDS patients, preventing opportunistic infections and prolonging life. In fact, combination treatment has led to a decline in AIDS incidence and mortality in the United States. Preliminary studies suggest that new regimens using a combination of two newly developed, more powerful drugs may replace the triple-combination treatment.

Unfortunately, people in many parts of the world cannot afford these expensive drugs. According to the World Health Organization, more than 50% of HIV-infected individuals are not receiving treatment. As a result, the AIDS epidemic continues to grow.

Another serious problem has been the emergence of drug-resistant HIV viruses. Worldwide containment of the AIDS epidemic will require an effective vaccine that prevents the spread of HIV. Developing such a vaccine remains a daunting challenge for immunologists. About 60 vaccines have been developed and tested clinically, but none has proved effective. An effective vaccine would have to counteract HIV's destruction of the key cells needed to launch an immune response. Also, because mutations arise at a very high rate, new viral strains with new antigens evolve quickly. A vaccine might quickly become obsolete. Some optimism has been generated by a combination of vaccine and gene therapy that has been tested in simian monkeys.

While immunologists work to develop a successful vaccine and more effective drugs to treat infected patients, massive educational programs have been launched to control, or slow, the spread of HIV. Educating the public that having multiple sexual partners increases the risk of HIV and teaching sexually

active individuals the importance of “safe sex” help contain the pandemic. In some countries public health facilities provide free condoms to those who are sexually active and free needles and syringes to those addicted to intravenous drugs. Some HIV prevention programs now provide male circumcision, which reduces the risk of HIV infection through sexual contact. The cost of these measures is far less than the cost of medical care for increased numbers of HIV patients.

In an autoimmune disease, the body attacks its own tissues

Self-tolerance, the ability to recognize self, is established during lymphocyte development. Lymphocytes do not normally attack cells and tissues of their own body. However, some lymphocytes do have the potential to be *autoreactive*, that is, to launch an immune response against self-tissues. In about 5% of adults in high-income countries, such autoreactivity can lead to a form of hypersensitivity known as *autoimmunity*, or **autoimmune disease**, in which immune cells react against the body's own cells. Some of the diseases that result from such failure in self-tolerance are rheumatoid arthritis, systemic lupus erythematosus, insulin-dependent diabetes, scleroderma, and multiple sclerosis.

In autoimmune diseases, antibodies and T cells attack the body's own tissues. In *rheumatoid arthritis*, T cells in the area of inflammation produce a cytokine that promotes inflammation. In addition, antibodies to a joint protein may generate antigen–antibody complexes that are deposited in the small joints. In *multiple sclerosis*, an autoimmune disease of the central nervous system, T_H cells attack an individual's own myelin antigens. MRI scans show the loss of myelin sheaths in multiple areas around axons in the brain and spinal cord that are normally myelinated. Scar tissue forms and compromises the ability of these damaged neurons to transmit signals.

Multiple genes, including MHC alleles, contribute to the development of autoimmune disease. Mutations that cause abnormal apoptosis or inadequate clearing of dead cells may result in danger signals that activate the immune system. Another important factor is that viral or bacterial infection often precedes the onset of an autoimmune disease. A tactic known as *molecular mimicry* has evolved in some pathogens. They trick the body by producing molecules that look like self-molecules. For example, an adenovirus that causes respiratory and intestinal illness produces a peptide that mimics myelin protein. When the body launches responses to the adenovirus peptide, it may also begin to attack the similar self-molecule, myelin.

As we have discussed, the numerous types of cells, regulatory and signaling molecules, and the complex actions of the immune system must be carefully regulated to maintain health. For example, specific T cells and B cells proliferate and respond to challenges by pathogens, but after an effective immune response, the expanded populations of T cells and B cells must be decreased to normal numbers. Cells that are no longer needed die by apoptosis. Overactivation of critical components can result in inflammation and autoimmune disease. Underactivation allows pathogens to cause serious disease. Either situation can be fatal.

Rh incompatibility can result in hypersensitivity

Named for the rhesus monkeys in whose blood it was first found, the Rh system consists of more than 40 kinds of Rh antigens, each referred to as an **Rh factor**. By far the most important of these factors is *antigen D*. About 85% of U.S. residents who are of Western European descent are Rh positive, meaning that they have antigen D on the surfaces of their red blood cells (in addition to the antigens of the ABO system and other blood group antigens). The 15% or so of this population who are Rh negative have no antigen D.

Unlike the situation discussed in Chapter 11 for the ABO blood group, Rh-negative individuals do not routinely produce antibodies against antigen D (anti-D). However, they do produce anti-D antibodies when they are exposed to Rh-positive blood. The allele coding for antigen D is dominant to the allele for the absence of antigen D. For this reason, Rh-negative people are homozygous recessive, and Rh-positive people are heterozygous or homozygous dominant.

Although several kinds of maternal–fetal blood type incompatibilities are known, **Rh incompatibility** is the most serious (FIG. 45-16). If a woman is Rh negative and the father of the fetus she is carrying is Rh positive, the fetus may also be Rh positive, having inherited the D allele from the father. Ordinarily, the maternal and fetal blood do not mix; nutrients, oxygen, and other substances are exchanged between the

two circulatory systems across the placenta. However, late in pregnancy or during the birth process, a few drops of blood from the fetus may pass through a defect in the placenta.

When maternal blood mixes with fetal blood, fetal red blood cells, which bear antigen D, activate the mother's immune system. The mother's B cells then produce antibodies to antigen D. If the woman becomes pregnant again, anti-D antibodies cross the placenta and enter the fetal blood. They combine with antigen D molecules on the surface of the fetal red blood cells, causing hemolysis (cells rupture and release hemoglobin into the circulation). The ability to transport oxygen is reduced, and breakdown products of the released hemoglobin damage organs, including the brain. In extreme cases of this disease, known as *erythroblastosis fetalis*, so many fetal red blood cells are destroyed that the fetus may die.

When Rh-incompatibility problems are suspected, fetal blood can be exchanged by transfusion before birth, but it is a risky procedure. More commonly, Rh-negative women are treated just after childbirth (or at termination of pregnancy by miscarriage or abortion) with a preparation of anti-D antibodies known as RhoGAM. These antibodies clear the Rh-positive fetal red blood cells from the mother's blood very quickly, minimizing the chance for her own white blood cells to become sensitized and develop memory cells. The antibodies are also soon eliminated from her body. As a result, if she becomes pregnant again, her blood does not contain the anti-D that could harm the developing fetus.

Figure 45-16 Rh incompatibility

When an Rh-negative woman produces Rh-positive offspring, her immune system may become sensitized. In subsequent pregnancies, she may produce anti-D antibodies that cross the placenta and destroy fetal red blood cells.

Allergic reactions are directed against ordinary environmental antigens

About 20% of the U.S. population is plagued by an allergic disorder, such as allergic asthma or hay fever. A predisposition toward these disorders appears to be inherited. In *allergic reactions* hypersensitivity results in the manufacture of antibodies against mild antigens, called **allergens**, which normally do not stimulate an immune response. Common environmental agents, such as pollen, house-dust mites, roach feces, and pet dander, can trigger allergic reactions in some individuals. In many kinds of allergic reactions, distinctive IgE immunoglobulins are produced.

Let us examine a common allergic reaction, *allergic rhinitis*, commonly known as hay fever. This allergic response is triggered in some individuals by breathing pollen (FIG. 45-17). Exposure to pollen causes *sensitization*. Macrophages degrade the allergen and present fragments of it to T cells. The activated T cells then stimulate B cells to become plasma cells and produce pollen-specific IgE. These antibodies attach to receptors on mast cells. The Fc end of each IgE molecule attaches to a mast cell receptor; its V region is free to combine with the pollen allergen.

Figure 45-17 An allergic reaction

Many people respond to breathing pollen by exhibiting symptoms of allergic rhinitis (hay fever), a common type of allergic reaction.

When a sensitized, allergic person inhales the microscopic pollen, allergen molecules rapidly attach to the IgE on sensitized mast cells. The IgE antibody then binds with the allergen. In response, mast cells release granules filled with histamine and other molecules that stimulate inflammation. Blood vessels dilate, and capillaries become more permeable, leading to edema and redness. Such responses cause the nasal passages to become swollen and irritated. A runny nose, sneezing, watery eyes, and a general feeling of discomfort are common.

A prolonged allergic response occurs when neutrophils are attracted by chemical compounds released by the mast cells. Neutrophils migrate to the inflamed area and release compounds that lengthen the allergic reaction.

In **allergic asthma**, an allergen–IgE response occurs in the bronchioles of the lungs. Mast cells release substances that cause smooth muscle to contract, and the airways in the lungs sometimes constrict for several hours, making breathing difficult. Mast cells also secrete compounds that cause inflammation. Allergic asthma is treated with steroids, which block cytokine production and reduce inflammation. Monoclonal antibodies to IgE are also useful in treating allergic asthma because they reduce IgE levels in the blood.

Certain foods or drugs act as allergens in some people, causing a reaction in the walls of the digestive tract that leads to discomfort

and diarrhea. When allergens are absorbed, they can cause mast cells to release granules elsewhere in the body. When the allergen–IgE reaction takes place in the skin, the histamine released by mast cells causes the swollen red welts known as urticaria, or hives.

Systemic anaphylaxis is a dangerous allergic reaction that can occur when a person develops an allergy to a specific drug, such as penicillin; to compounds in the venom injected by a stinging insect; or even to certain foods. Within minutes after the substance enters the body, a widespread allergic reaction takes place. Mast cells release large amounts of histamine and other compounds into the circulation, causing extreme vasodilation and capillary permeability. So much plasma may be lost from the blood that circulatory shock and death can occur within a few minutes. Epinephrine (adrenaline) must be rapidly injected to reverse anaphylactic symptoms.

The symptoms of allergic reactions are often treated with corticosteroids and antihistamines, drugs that block the effects of histamine. These drugs compete for the same receptors on cells targeted by histamine. When the antihistamine combines with the receptor, it blocks the histamine from binding, thus preventing its harmful effects. Antihistamines are useful clinically in relieving the symptoms of hives and hay fever. They are not completely effective because mast cells release molecules other than histamine that also cause allergic symptoms.

Graft rejection is an immune response against transplanted tissue

Skin can be successfully transplanted from one part of the same body to another or from one identical twin to another. However, when skin is taken from one person and grafted onto the body of a non-twin, it is rejected and sloughs off. Why? Recall that tissues from the same individual or from identical twins have identical HLA alleles and thus the same HLA antigens. Such tissues are compatible. Because there are many alleles for each of the HLA genes, it is difficult to find identical matches among individuals who are not identical twins.

When a tissue or organ is taken from a donor and transplanted to the body of another person, several of the HLA antigens are likely to be different. The recipient's immune system regards the graft as foreign and launches an immune response known as **graft rejection**. In the first stage of rejection, the *sensitization stage*, T_H cells and T_C cells recognize the foreign antigens. In the second stage, the *effector stage*, T_C cells, the complement system, and cytokines secreted by T_H cells attack the transplanted tissue and can destroy it within a week. The sequence of events in graft rejection can be summarized as follows:

tissue from donor transplanted into body of recipient → T_H cells and T_C cells recognize HLA antigens on transplant cells as foreign → T_H cells secrete cytokines, complement system is activated, and T_C cells destroy transplant cells

To avoid graft rejection, tissues from the patient and from potential donors must be typed and matched as closely as possible. Cell typing is somewhat similar to blood typing but is more complex. If all the HLA antigens are matched, the graft has about a 95% chance of surviving the first year. Unfortunately, not many people are lucky enough to have an identical twin to supply spare parts, so perfect matches are difficult to find. Furthermore, some organs, such as the heart, cannot be spared. Most transplanted organs therefore come from unrelated donors, often from patients who have just died.

To prevent graft rejection in less compatible matches, physicians use antirejection drugs such as cyclosporine to suppress the immune system. Cyclosporine prevents T cells

from producing cytokines. Unfortunately, immunosuppression makes the transplant patient more vulnerable to pneumonia or other infections and increases the risk of certain types of cancer. After the first few months, immunosuppressant drug dosages may be reduced. Researchers are working to develop more effective immunosuppression techniques involving gene therapy and CRISPR/Cas9 technology.

In the United States, thousands of patients are in need of organ transplants. Because the number of human donors does not meet this need, investigators are developing techniques for culturing stem cells as replacement tissues. Current research is promising for successful human tissue and organ replacement in the future using a patient's own stem cells. Medical engineers also continue to develop effective artificial organs.

Some researchers are working on more effective methods for transplanting animal tissues and organs to humans. Other investigators plan to introduce human stem cells into animal embryos in order to produce human organs in animals. These organs would eventually be harvested and implanted in humans.

The body has a few immunologically privileged locations where foreign tissue is accepted. For example, corneal transplants are highly successful because the cornea has almost no associated blood or lymphatic vessels and is thus out of reach of most lymphocytes. Furthermore, antigens in the corneal graft probably would not find their way into the circulatory system and therefore could not stimulate an immune response.

CHECKPOINT 45.6

- How do cancer cells evade the immune system?
- How does HIV infect the body? How does the immune system respond?
- How does an autoimmune disease develop?
- **VISUALIZE** Draw the sequence of immunological events that take place in a common type of allergic reaction, such as hay fever.
- **CONNECT** What is the immunological basis for graft rejection?

Summary: Focus on Learning Objectives

45.1 Evolution of Immune Responses (page 963)

1 Distinguish between innate and adaptive immunity.

- The **immune system** is the internal defense system; it consists of the cells and molecules that recognize foreign or dangerous macromolecules and respond to eliminate them. **Immune responses** are the body's defensive responses against foreign macromolecules, including **pathogens** (disease-causing organisms), cancer cells, toxins, and other harmful agents.
- Innate immunity** provides general and immediate protection against foreign macromolecules, including pathogens, some toxins and drugs, and cancer cells.
- Adaptive immunity** targets distinct **antigens**, molecules recognized as foreign or dangerous by cells of the immune system. The adaptive immune system produces **antibodies**, highly specific proteins that recognize and bind to specific antigens.
- Another defining feature of adaptive immunity is **immunological memory**; that is, the system “remembers” foreign or dangerous molecules and responds more strongly to repeated encounters with the same molecules.

2 Compare, in general terms, the immune responses that have evolved in invertebrates and vertebrates.

- Invertebrates depend mainly on innate immune responses, such as physical barriers; **phagocytosis** (engulfing and destroying pathogens); receptors that recognize molecular patterns associated with pathogens; and **antimicrobial peptides** (soluble molecules that destroy pathogens).
- Vertebrates use both innate and adaptive immune responses.

45.2 Innate Immune Responses in Vertebrates

(page 965)

3 Describe innate immune responses, including physical barriers; recognition by pattern recognition receptors; actions of phagocytes and other cells; actions of cytokines and complement; and the inflammatory response.

- Innate immune responses include physical barriers, such as the skin and the epithelial linings of the respiratory and digestive tracts. Antimicrobial peptides are produced by epithelial membranes.
- When pathogens break through the first-line defenses, **pathogen-associated molecular patterns**, or **PAMPs**, bind with **pattern recognition receptors (PRRs)**; this binding activates other innate defenses. PAMPs are sets of common molecular features that are characteristic of each class of pathogen. The best known pattern recognition receptors are **Toll-like receptors**, receptors on phagocytes and certain other types of cells.
- Phagocytes**, including **neutrophils** and **macrophages**, destroy bacteria. **Natural killer (NK) cells** destroy cells infected with viruses and foreign or altered cells such as tumor cells. **Dendritic cells** release antiviral proteins called **interferons**.

- Cytokines** are signaling proteins that regulate interactions between cells. Important groups include interferons, tumor necrosis factors, interleukins, and chemokines. Interferons inhibit viral replication and activate natural killer cells. **Tumor necrosis factor (TNF)** stimulates immune cells to initiate an inflammatory response. **Interleukins** help regulate interactions between lymphocytes and other cells of the body, help mediate inflammation, and can mediate fever. **Chemokines** attract, activate, and direct the movement of certain cells of the immune system.
- Complement** proteins lyse the cell walls of pathogens; coat pathogens, thereby enhancing phagocytosis; and attract white blood cells to the site of infection. These actions enhance the inflammatory response.
- When pathogens invade tissues, they trigger an **inflammatory response**, which includes three main processes: vasodilation, which brings more blood to the area of infection; increased capillary permeability, which allows fluid and antibodies to leave the circulation and enter the tissues; and increased phagocytosis. In response to infection, **mast cells** release **histamine** and other compounds that cause vasodilation and increased capillary permeability.

45.3 Adaptive Immune Responses in Vertebrates

(page 969)

4 Contrast cell-mediated and antibody-mediated immunity and give an overview of each process.

- In **cell-mediated immunity**, specific T cells are activated; T cells release proteins that destroy cells infected with viruses or other intracellular pathogens.
- In **antibody-mediated immunity**, specific B cells are activated; B cells multiply and differentiate into plasma cells, which produce antibodies.

5 Describe the functions of the specialized cells of the adaptive immune system and of the major histocompatibility complex.

- Two main types of cells important in adaptive immune responses are lymphocytes and antigen-presenting cells. Lymphocytes develop from stem cells in the bone marrow. **T cells** are lymphocytes responsible for cell-mediated immunity. The **thymus gland** confers immunocompetence on T cells by making them capable of distinguishing between self and nonself. The types of T cells include **T cytotoxic cells (T_C cells)**, **T helper cells (T_H)**, **memory T_C cells**, **memory T_H cells**, and **regulatory T cells (T_{regs})**. T cells are distinguished by their **T-cell receptors (TCRs)**.
- B cells** are lymphocytes responsible for antibody-mediated immunity. B cells differentiate into **plasma cells**, which produce antibodies. Some activated B cells become **memory B cells**, which continue to produce antibodies after the body overcomes the infection.
- Antigen-presenting cells (APCs)**, including dendritic cells, macrophages, and B cells, display foreign antigens as

well as their own surface proteins. Dendritic cells are specialized to process, transport, and present antigens.

- Immune responses depend on the **major histocompatibility complex (MHC)**, a group of genes that encode MHC proteins. In humans the MHC is called the **human leukocyte antigen complex (HLA)**.

45.4 Cell-Mediated Immunity (page 972)

6 Describe the sequence of events in cell-mediated immunity.

- In cell-mediated immunity, specific T cells are activated by a foreign antigen–MHC complex on the surface of an infected cell. A *co-stimulatory molecule* and interleukins are also required.
- Activated T_C cells multiply and give rise to a clone, a process called **clonal expansion**. These differentiated cells migrate to the site of infection and destroy pathogen-infected cells. Activated T_H cells give rise to a clone of T_H cells, which secrete cytokines that activate B cells and macrophages.

45.5 Antibody-Mediated Immunity (page 973)

7 Summarize the sequence of events in antibody-mediated immunity, including the effects of antigen–antibody complexes on pathogens.

- In antibody-mediated immunity, B cells are activated when they combine with antigen. Activation requires both an APC (such as a dendritic cell or macrophage) that has a foreign antigen–MHC complex displayed on its surface and a T_H cell that secretes interleukins.
- When activated B cells multiply, they give rise to clones of cells. The cloned cells differentiate and form plasma cells. Plasma cells produce specific antibodies, called **immunoglobulins (Ig)**, in response to the specific antigens that activated them.
- An antibody combines with a specific antigen to form an *antigen–antibody complex*, which may inactivate the pathogen, stimulate phagocytosis, or activate the complement system.

8 Describe the basic structure and function of an antibody and explain the basis of antibody diversity.

- An antibody molecule consists of four polypeptide chains: two identical heavy chains and two shorter light chains. Each chain has a *constant (C) region* and a *variable (V) region*. In a Y-shaped antibody, the two arms combine with antigen.

- Rearrangement of DNA segments during the differentiation of B cells is the main factor responsible for antibody diversity; millions of different types of B (and T) cells are produced.

9 Describe the basis of immunological memory and contrast secondary and primary immune responses.

- After an infection, memory B cells and memory T cells remain in the body. These cells are responsible for long-term immunity.
- The first exposure to an antigen stimulates a **primary immune response**. A second exposure to the same antigen evokes a **secondary immune response**, which is more rapid and more intense than the primary response.

10 Compare active and passive immunity, and give examples of each.

- **Active immunity** develops as a result of exposure to antigens; it may occur naturally after recovery from a disease or can be artificially induced by immunization with a vaccine.
- **Passive immunity** is a temporary condition that develops when an individual receives antibodies produced by another person or animal.

45.6 Response to Disease, Immune Failures, and Harmful Reactions (page 980)

11 Describe the body's response to cancer cells and HIV.

- NK cells, macrophages, T cells, and other cells of the immune system recognize antigens on cancer cells and launch an immune response against them. Cancer cells evade the immune system by blocking T_C directly or by decreasing the class I MHC molecules on T_C cells.
- **Acquired immunodeficiency syndrome (AIDS)** is caused by the **human immunodeficiency virus (HIV)**, a retrovirus. HIV destroys T helper cells, severely impairing immunity and placing the patient at risk for opportunistic infections.

12 Describe examples of hypersensitivity, including autoimmune diseases, Rh incompatibility, and allergic reactions, and summarize the immunological basis of graft rejection.

- In **autoimmune diseases**, the body reacts immunologically against its own tissues.
- When an Rh-negative woman gives birth to an Rh-positive baby, she may develop anti-D antibodies. Rh incompatibility can then occur in future pregnancies.
- In an **allergic reaction**, an **allergen** stimulates the production of IgE, which combines with receptors on mast cells. The mast cells release histamine and other molecules that cause inflammation and other symptoms of allergy. **Systemic anaphylaxis** is a rapid, widespread allergic reaction that can lead to death.
- Transplanted tissues have HLA antigens that stimulate **graft rejection**, an immune response in which T cells destroy the transplant.

Test Your Understanding

Know and Comprehend

1. Innate immune responses include all but (a) inflammation (b) antigen–antibody complexes (c) binding of PAMPs with pattern recognition receptors (d) complement (e) phagocytosis
2. Cytokines (a) are regulatory Toll-like receptors (b) prevent the inflammatory response (c) include interferons and interleukins (d) are immunoglobulins (e) b and c are correct
3. Which of the following is *not* an action of complement? (a) enhances phagocytosis (b) enhances inflammatory response (c) coats pathogens (d) lyses viruses (e) stimulates production of memory T cells
4. Which of the following cells are antigen-presenting cells? (a) NK cells and monocytes (b) macrophages and plasma cells (c) dendritic cells and macrophages (d) mast cells and B cells (e) memory T cells and plasma cells
5. Which of the following cells are especially adept at destroying tumor cells? (a) NK cells (b) plasma cells (c) neutrophils (d) B cytotoxic cells (e) mast cells
6. The major histocompatibility complex (MHC) (a) consists of Y-shaped molecules (b) encodes certain antibodies (c) encodes Toll-like receptors (d) inhibits complement release from macrophages (e) encodes a group of cell-surface proteins.
7. Immunoglobulin A (a) recognizes pathogen-associated molecular patterns (b) binds with NK cells (c) prevents pathogens from attaching to epithelial surfaces (d) is found mainly on dendritic cell surfaces (e) is found mainly on T-cell surfaces
8. When a person is exposed to the same antigen a second time, the response is (a) less specific than the first time (b) more rapid than the first time (c) mediated by dendritic cells (d) likely to lead to development of an autoimmune disease (e) a hypersensitivity reaction
9. In an allergic reaction, (a) an allergen binds with IgE (b) the body is immunodeficient (c) T helper cells release histamine (d) allergens are produced by plasma cells (e) mast cells are deactivated

Apply and Analyze

10. Which sequence most accurately describes antibody-mediated immunity? 1. B cell divides and gives rise to clone 2. antibodies produced 3. cells differentiate and form plasma cells 4. activated T helper cell interacts with B cell displaying same antigen complex 5. B cell activated (a) 1, 2, 3, 4, 5 (b) 3, 2, 1, 4, 5 (c) 4, 5, 3, 2, 1 (d) 4, 5, 1, 3, 2 (e) 4, 3, 1, 2, 5
11. **VISUALIZE** Label the following diagram and explain what this diagram illustrates.

12. Specificity, diversity, and memory are key features of the immune system. Giving specific examples, explain how each of these features is important.
13. **PREDICT** What would be the effects of a significant reduction of macrophages in the body? Which do you think would have a greater effect on the immune system: significant decrease of macrophages or of memory B cells?
14. **PREDICT** A playmate in kindergarten exposes John and Jack to measles. John has been immunized against measles, but Jack has not received the measles vaccine. How are their immune responses different? Five years later, John and Jack are playing together when Judy, who is coming down with measles, sneezes on both of them. Is it probable that either John or Jack will become ill with measles?

Evaluate and Synthesize

15. **EVOLUTION LINK** The enzymes Rag1 and Rag2 cut and rearrange DNA, producing millions of specific antibodies and T-cell receptors. Immunologists thought that the genes (*Rag1* and *Rag2*) that encode these enzymes were found only in jawed vertebrates. However, investigators have found similar genes in the purple sea urchin. What does this finding suggest about the evolution of the adaptive immune system?
16. **SCIENCE, TECHNOLOGY, AND SOCIETY** Imagine that you are a researcher developing new HIV treatments. What approaches might you take? What public policy decisions would you recommend that might help slow the spread of HIV while new treatments or vaccines are being developed? What role might technology play in slowing the spread of HIV?

46 Gas Exchange

To stay alive, animals must take in oxygen and release excess carbon dioxide. Most animal cells require a continuous supply of oxygen for cellular respiration. Brain cells may be seriously damaged if their oxygen supply is cut off for only a few minutes. The exchange of gases between an organism and its environment is called **respiration**.

There are two phases of respiration. During **organismic respiration**, oxygen from the environment is taken up by the animal and delivered to its individual cells. At the same time, carbon dioxide generated during *cellular respiration* is excreted into the environment. **Aerobic cellular respiration** takes place in mitochondria. Oxygen is essential because it serves as the final electron acceptor in the mitochondrial electron transport chain (see Chapter 8). Recall that carbon dioxide is a metabolic waste product of cellular respiration.

Sponges, hydras, flatworms, and many other small, aquatic organisms exchange gases entirely by simple diffusion. Recall that **diffusion** is the passive movement of particles (atoms, ions, or molecules) from a region of higher concentration of a particular kind of particle to a region of lower concentration of that particle, that is, down its concentration gradient (see Chapter 5). In these animals most cells are in direct contact with the environment. Dissolved oxygen from the surrounding water diffuses into the cells, while carbon dioxide diffuses out of the cells and into the water. No specialized respiratory structures are needed.

In an animal more than about 1 mm thick, oxygen cannot diffuse quickly enough through the layers of cells to support life. Specialized respiratory structures, such as gills or lungs, deliver oxygen to the cells or to a transport system. These structures also facilitate excretion

KEY CONCEPTS

- 46.1** Air has a higher concentration of molecular oxygen than water does, and animals require less energy to move air than to move water over a gas exchange surface; however, animals that respire in air must have adaptations that reduce water loss so that their respiratory surfaces do not dry out.
- 46.2** Adaptations for gas exchange include a thin, moist body surface; gills in aquatic animals; and tracheal tubes and lungs in terrestrial animals.
- 46.3** In mammals, oxygen and carbon dioxide are exchanged between alveoli and blood by diffusion; the pressure of a particular gas determines its direction and rate of diffusion. Respiratory pigments combine with oxygen and transport it; carbon dioxide is transported mainly as bicarbonate ions.
- 46.4** Several defense mechanisms protect the lungs from harmful substances that are inhaled; tobacco smoke and other air pollutants are major causes of disease, disability, and death.

PHOTO: Elephant seal (*Mirounga leonina*) releasing its warm breath into freezing air. The water vapor in the exhaled air condenses into liquid water and ice; it can be seen as a small cloud. Photographed at Gold Bay, South Georgia Island, Antarctic Ocean, Antarctica. John Bryant/Getty Images

of carbon dioxide. Lungs are an adaptation for gas exchange in terrestrial environments (see photograph).

In many animal groups, including vertebrates, respiratory systems and circulatory systems are functionally connected. They work together to provide efficient intake and transport of oxygen. Such systems provide sufficient oxygen to support high metabolic rates. As we will discuss, different strategies for gas exchange have evolved in the arthropods.

In this chapter we will examine adaptations for gas exchange in air and water and describe various types of respiratory surfaces. We will then focus on the structure and function of the mammalian respiratory system. We end the chapter with a discussion of the effects of breathing polluted air, including cigarette smoke.

46.1 Adaptations for Gas Exchange in Air or Water

LEARNING OBJECTIVE

- 1 Compare the advantages and disadvantages of air and water as mediums for gas exchange and describe adaptations for gas exchange in air.

Gas exchange in air has certain advantages over gas exchange in water. Air contains a much higher concentration of molecular oxygen (at least 20 times more) than water does. In addition, oxygen diffuses about 10,000 times faster through air than through water. Another advantage is that less energy is needed to move air than to move water over a gas exchange surface because air is less dense and less viscous. A mammal uses less than 2% of its energy budget to breathe compared to a fish, which must spend as much as 20% of its energy to obtain its oxygen from water.

Gas exchange in air presents a major challenge: the threat of desiccation (becoming extremely dry). Animals that respire in air struggle continuously with water loss. Respiratory surfaces must be kept moist because oxygen and carbon dioxide are dissolved in the fluid that bathes the cells of these surfaces. Whether an animal makes its home on land or water, gas exchange takes place across a moist surface.

Adaptations have evolved that keep respiratory surfaces moist and minimize desiccation. For example, the lungs of air-breathing vertebrates are located deep within the body, not exposed as gills are. Air is humidified and brought to body temperature as it passes through the moist upper respiratory passageways. Expired air must again pass through these airways (providing opportunity for retaining water) before leaving the body. These adaptations protect the lungs from the drying and cooling effects of air.

CHECKPOINT 46.1

- What are some advantages of gas exchange in air over gas exchange in water?

46.2 Types of Respiratory Surfaces

LEARNING OBJECTIVE

- 2 Describe the following adaptations for gas exchange: body surface, tracheal tubes, gills, and lungs.

Respiratory structures must be moist and must also have thin walls through which diffusion can easily occur. Four main types of respiratory surfaces have evolved in animals: the animal's own body surface, tracheal tubes, gills, and lungs (**FIG. 46-1**). Some animals use a combination of these adaptations. Gills are adapted for gas exchange in water, and the tracheal tubes of insects and lungs of vertebrates are respiratory structures adapted for gas exchange in air. With the important exception of insect tracheal tubes, respiratory structures are richly supplied with blood vessels that facilitate exchange and transport of respiratory gases.

Most animals carry on **ventilation**; that is, they actively move air or water over their respiratory surfaces. If the air or water supplying oxygen to the cells can be continuously renewed, more oxygen will be available. Sponges use their flagella to set up a current of water through the channels of their bodies. Most fishes gulp water, which then passes over their gills. Terrestrial vertebrates have lungs and breathe air. When mammals breathe, the diaphragm and other muscles move air in and out of the lungs.

The body surface may be adapted for gas exchange

Gas exchange occurs through the entire body surface in many animals, including nudibranch mollusks, most annelids, and some amphibians. These animals are small, with a high ratio of surface area to volume. They also have a low metabolic rate that requires smaller quantities of oxygen per cell. In aquatic animals, the body surface is kept moist by the surrounding water. In some terrestrial animals, the body secretes fluids that keep its surface moist. Many animals that exchange gases across the body surface also have gills or lungs.

Tracheal tube systems deliver air directly to the cells

In insects and some other arthropods (such as centipedes and millipedes, some mites, and some spiders), the respiratory system is a network of **tracheal tubes**, also called **tracheae** (**FIG. 46-2**). This very efficient respiratory system delivers air directly to the cells. Air enters the tracheal tubes through a series of as many as 20 tiny openings called **spiracles** along the body surface. In some insects, especially large, active ones, muscles help ventilate the tracheae by pumping air in and out of the spiracles. For example, the grasshopper draws air in through the first four pairs of spiracles when the abdomen expands. Then the abdomen contracts, forcing air out through the last six pairs of spiracles.

(a) Body surface. Some small, multicellular animals exchange gases through the body surface.

(b) Tracheal tubes. Insects and some other arthropods exchange gases through a system of tracheal tubes, or tracheae.

(c) Gills. Most aquatic animals exchange gases through gills, thin structures that extend from the body surface. Gills can be internal or external.

(d) Lungs. Lungs are adaptations for gas exchange in terrestrial habitats.

Figure 46-1 Adaptations for gas exchange

The efficient tracheal tube system of insects delivers air directly to the cells.

(a) Location of spiracles and tracheal tubes. Air enters the system of tracheal tubes through openings called spiracles.

(b) Structure and function of tracheal tubes. Air passes through a system of branching tracheal tubes that conduct oxygen to all cells of the insect.

(c) SEM of a mole cricket trachea. Rings of chitin reinforce the tubes of the tracheal system, preventing their collapse.

Figure 46-2 Gas exchange in insects: tracheal tubes

CONNECT In contrast to vertebrate gas exchange, blood does not play an essential role in insect gas exchange. Why?

Once inside the body, the air passes through a system of branching tracheal tubes, which extend to all parts of the animal. The tracheal tubes terminate in microscopic, fluid-filled tracheoles. Gases are exchanged between this fluid and the body cells. The tracheal system supplies enough oxygen to support the high metabolic rates required by many insects.

Gills are the respiratory surfaces in many aquatic animals

Found mainly in aquatic animals, **gills** are moist, thin structures that extend outward from the body surface. They are supported by the buoyancy of water but tend to collapse in air. In many animals, the outer surface of the gills is exposed to water, whereas the inner side is in close contact with networks of blood vessels.

Sea stars and sea urchins have *dermal gills* that project from the body wall. Their ciliated epidermal cells ventilate the gills by beating a stream of water over them. Gases are exchanged between the water and the fluid inside the coelom by diffusion through the gills.

Various types of gills are found in some annelids, aquatic mollusks, crustaceans, fishes, and amphibians. Mollusk gills are folded, providing a large surface for respiration. In clams and other bivalve mollusks and in simple chordates, gills may also be adapted for trapping and sorting food. The rhythmic beating of cilia draws water over the gill area, and food is filtered out of the water while gases are exchanged. In mollusks, gas exchange also takes place through the mantle.

In chordates, gills are usually internal. A series of slits perforates the pharynx, and the gills lie along the edges of these gill slits (see Fig. 32-4). In bony fishes, the fragile gills are protected by an external bony plate, the **operculum**. In some fishes, movements of the jaw and operculum help pump water rich in oxygen through the mouth and across the gills. The water leaves through the gill slits.

Each gill in the bony fish consists of many *gill filaments*, which provide an extensive surface for gas exchange (FIGS. 46-3a and b). The filaments extend out into the water, which continuously flows over them. A capillary network delivers blood to the gill filaments, facilitating diffusion of oxygen and carbon dioxide between blood and water. This system is extremely efficient because blood flows in a direction opposite to the movement of the water. This arrangement, called a **countercurrent exchange system**, maximizes the difference in oxygen concentration between blood and water throughout the area where the two remain in contact (FIG. 46-3c).

If blood and water flowed in the *same* direction—that is, *concurrent exchange*—the difference between the oxygen concentrations in blood (low) and water (high) would be very large initially and then very small at the end (FIG. 46-3d). The oxygen concentration in the water would decrease as the concentration in the blood increased. When the concentrations in the two fluids became equal, equilibrium would be reached, and the net diffusion of oxygen would stop. Only about 50% of the oxygen dissolved in the water could diffuse into the blood.

In the countercurrent exchange system, however, blood low in oxygen comes in contact with water that is partly

depleted of oxygen. Then, as the blood flowing through the capillaries becomes progressively richer in oxygen, the blood comes in contact with water with an increasingly higher concentration of oxygen. Thus, all along the capillaries, the diffusion gradient favors passage of oxygen from the water into the gill. A high rate of diffusion is maintained, ensuring that a very high percentage (more than 80%) of the available oxygen in the water diffuses into the blood.

Oxygen and carbon dioxide do not interfere with each other's diffusion, and they simultaneously diffuse in opposite directions. The reason is that oxygen is more concentrated outside the gills than inside but carbon dioxide is more concentrated inside the gills than outside. Thus, the same countercurrent exchange mechanism that ensures efficient inflow of oxygen also results in equally efficient outflow of carbon dioxide.

Terrestrial vertebrates exchange gases through lungs

Lungs are respiratory structures that develop as ingrowths of the body surface or from the wall of a body cavity such as the pharynx (throat region). For example, the *book lungs* of spiders are enclosed in an inpocketing of the abdominal wall. These lungs consist of a series of thin, parallel plates of tissue (like the pages of a book) filled with hemolymph (see Fig. 46-1d). The plates of tissue are separated by air spaces that receive oxygen from the outside environment through a spiracle. A different type of lung evolved in land snails and slugs. (These terrestrial mollusks lack gills.) Gas exchange takes place through a lung, which is a vascular region of the mantle.

Fossil evidence suggests that early lobe-finned fishes had lungs somewhat similar to those of modern lungfishes. The Australian lungfish can use either its gills or its lungs, depending on the conditions in its environment. The gills of African and South American lungfishes degenerate with age, so adults must rise to the surface and exchange gases entirely through their lungs. Some paleontologists hypothesize that all early bony fishes had lungs or lunglike structures. Most modern bony fishes have no lungs, but nearly all have homologous **swim bladders** (see Chapter 32). By adjusting the amount of gas in its swim bladder, the fish can control its buoyancy.

Most amphibians have lungs (FIG. 46-4). However, most of their gas exchange takes place across the body surface. The lungs of salamanders are two long, simple sacs richly supplied with capillaries. Frogs and toads have ridges containing connective tissue on the inside of the lungs, which increases the respiratory surface. Some amphibians do not have lungs. Among plethodontid (lungless) salamanders, for example, gas exchange takes place across the thin, wet skin and through the moist, vascular walls of the mouth and pharynx.

Non-avian reptile lungs are more developed than amphibian lungs. The respiratory surface of each lung is divided into large sacs that increase the surface for gas exchange. In some turtles, lizards, and crocodiles, the lungs have many subdivisions that give them a spongy texture. Non-avian reptiles ventilate their lungs by drawing air into the lungs, but the muscles

Key Point

Countercurrent flow efficiently oxygenates blood circulating through the gill filaments.

(a) Location of gills. The gills form the lateral wall of the pharyngeal cavity. They lie under a bony plate, the operculum, which has been removed in this side view.

(b) Structure of a gill. Each gill consists of a cartilaginous gill arch to which two rows of leaflike gill filaments attach. Each gill filament has many smaller extensions rich in capillaries. As water flows past the gill filament, oxygen passes from the water into blood circulating through the capillaries.

(c) Countercurrent flow. Blood entering the capillaries of the gill filament is deficient in oxygen. The blood flows through the capillaries in a direction opposite to that taken by the water. This countercurrent exchange system efficiently charges the blood with oxygen.

(d) Concurrent flow (hypothetical). If the system were concurrent—that is, if blood flowed through the capillaries in the same direction as the flow of the water—much less of the oxygen dissolved in the water could diffuse into the blood.

(e) Gills of the salmon.

Figure 46-3 Gas exchange in bony fishes: gills

PREDICT In what way would you expect the countercurrent mechanism to affect the removal of CO_2 from the blood?

involved differ in the various reptile groups. Gas exchange is not very efficient and does not supply enough oxygen to sustain long periods of activity.

Birds have the most efficient respiratory system of any living vertebrate. Very active, endothermic animals with high

metabolic rates, birds require large amounts of oxygen to sustain flight and other activities. Their small, bright red lungs have extensions (usually nine) called *air sacs*, which reach into all parts of the body and even connect with air spaces in some of the bones. The air sacs act as bellows, drawing air into

Figure 46-4 Evolution of vertebrate lungs

During vertebrate evolution, the surface area of the lung increased. Salamander lungs are simple sacs. Other amphibians and reptiles have lungs with small ridges or folds that increase surface area. Birds have an elaborate system of lungs and air sacs. Mammalian lungs have millions of air sacs (alveoli) that increase the surface available for gas exchange (see Fig. 46-7).

the system. Collapse of the air sacs during exhalation forces air out. In birds, gas exchange does not take place across the walls of the air sacs.

The high-performance bird respiratory system is arranged so that air flows in one direction through the lungs and is renewed during a two-cycle process (FIG. 46-5). Air entering the body passes into the posterior air sacs and the part of the lungs closest to these air sacs. The posterior air sacs are reservoirs for fresh air. When the bird exhales, that air flows into the lungs. At the second breath, the air flows from the lungs to the anterior air sacs. Finally, at the second exhalation, the air leaves the body as another breath of air enters the lungs. Thus, a bird gets fresh air across its lungs through both inhalation and exhalation.

In birds, the narrowest branches of the airway end in tiny, thin-walled tubes called **parabronchi**. In contrast to the saclike alveoli of mammals, parabronchi are open at both ends and air continuously flows through them. Gas exchange takes place across the walls of these tubes, which are rich in capillaries. Chickens and other weak-flying birds have about 400 parabronchi per lung; pigeons and other strong-flying birds have about 1800 parabronchi per lung.

The direction of blood flow in the lungs is in a different direction from that of airflow through the parabronchi. This arrangement, similar in principle to the countercurrent exchange in the gills of fishes, increases the amount of oxygen that enters the blood. However, in birds, the capillaries are oriented at right angles to the parabronchi rather than along their length. For this reason, this arrangement is referred to as *crosscurrent* rather than countercurrent.

Figure 46-5 Gas exchange in birds

The bird respiratory system includes lungs and air sacs. The bird's breathing process requires two cycles of inhalation and exhalation to support a one-way flow of air through the lungs.

CHECKPOINT 46.2

- **CONNECT** Why are specialized respiratory structures necessary in a tadpole but not in a flatworm?
- How does gas exchange differ among the following animals: earthworm, grasshopper, fish, and bird?
- How does the countercurrent exchange system increase the efficiency of gas exchange between a fish's gills and blood?

46.3 The Mammalian Respiratory System

LEARNING OBJECTIVES

- 3 Trace the passage of oxygen through the human respiratory system from nostrils to alveoli.
- 4 Summarize the mechanics of breathing in humans and describe gas exchange in the lungs and tissues.
- 5 Summarize the mechanisms by which oxygen and carbon dioxide are transported in the blood and identify factors that determine the oxygen-hemoglobin dissociation curve.

Figure 46-6 The human respiratory system

The internal view of one lung illustrates a small portion of its extensive system of air passageways. The muscular diaphragm forms the floor of the thoracic cavity. The respiratory centers in the brain (medulla and pons) regulate the rate of respiration.

- 6 Describe the regulation of breathing in humans and summarize the physiological effects of hyperventilation and of sudden decompression when a diver surfaces too quickly from deep water.

The respiratory system of mammals consists of the lungs and a series of tubes through which air passes on its journey from the nostrils to the lungs and back (FIG. 46-6). The lungs have an enormous surface area. As in all vertebrates, the respiratory and circulatory systems are functionally connected. The circulatory system delivers oxygen-rich blood to all the cells in the body. In the following sections, we focus mainly on the human respiratory system.

The airway conducts air into the lungs

A breath of air enters the body through the *nostrils* and flows through the *nasal cavities*. Air passing through the nose is filtered, moistened, and brought to body temperature. The nasal cavities are lined with a moist, ciliated epithelium rich in blood vessels. Inhaled dirt, bacteria, and other foreign particles are trapped in the stream of mucus produced by cells within the epithelium and pushed along toward the throat by the cilia. In this way, foreign particles are delivered to the digestive system, which can more effectively dispose of such materials than can the delicate lungs. We normally swallow more than a pint of nasal mucus each day, and even more during an infection or allergic reaction.

The back of the nasal cavities is continuous with the throat region, or **pharynx**. Air finds its way into the pharynx whether we breathe through the nose or mouth. An opening in the floor of the pharynx leads into the **larynx**. Because the larynx contains the vocal cords, it is also referred to as the “voice box.” Cartilage embedded in its wall prevents the larynx from collapsing and makes it hard to the touch when felt through the neck.

During swallowing, a flap of tissue called the **epiglottis** automatically closes off the larynx so that food and liquid enter the esophagus rather than the lower airway. If this mechanism fails and foreign matter enters the sensitive larynx, a cough reflex expels the material. Despite these mechanisms, choking sometimes occurs.

From the larynx, air passes into the **trachea**, or windpipe, which is kept from collapsing by rings of cartilage in its wall. The trachea divides into two branches, the **bronchi** (sing., *bronchus*); one bronchus connects to each lung. Both trachea and bronchi are lined by a mucous membrane containing ciliated cells. These cells trap medium-sized particles that escape the cleansing mechanisms of the nose and larynx. Mucus containing these particles is constantly beaten upward by the cilia to the pharynx, where it is periodically swallowed. This mechanism, functioning as a cilia-propelled elevator of mucus, helps keep foreign material out of the lungs.

Gas exchange occurs in the alveoli of the lungs

The lungs are large, paired, spongy organs occupying the *thoracic* (chest) cavity. The right lung is divided into three lobes, the left lung into two lobes. Each lung is covered with a **pleural membrane**, which forms a continuous sac that encloses the lung and extends outward to become the lining of the thoracic cavity. The *pleural cavity* is the space between the pleural membranes. A film of fluid in the pleural cavity provides lubrication between the lungs and the chest wall.

Because the lung consists largely of air tubes and elastic connective tissue, it is a spongy, elastic organ with a very large internal surface area for gas exchange. Within each lung the bronchi branch and become progressively shorter, narrower, and more numerous, similar to the branching of a tree. Small branches give rise to the even smaller **bronchioles** in each lung. Each bronchiole ends in a cluster of tiny air sacs, the **alveoli** (sing., *alveolus*) (FIG. 46-7). Each human lung contains more than 200 million alveoli, which provide an internal surface area the approximate size of a tennis court!

Each alveolus is lined by an extremely thin, single layer of epithelial cells. Gases diffuse freely through the wall of the alveolus and into the capillaries that surround it. Only two thin cell layers—the endothelium of the alveolar wall and the epithelium of the capillary wall—separate the air in the alveolus from the blood.

In summary, air passes through the following sequence of structures after it enters the body:

nostrils → nasal cavities → pharynx → larynx → trachea → bronchi
→ bronchioles → alveoli

Ventilation is accomplished by breathing

Breathing is the mechanical process of moving air from the environment into the lungs and of expelling air from the lungs. Inhaling air is called **inhalation** or *inspiration*; exhaling air is **exhalation** or *expiration*. The thoracic cavity is closed so that air can enter only through the trachea. (When the chest wall is punctured, for example, by a fractured rib or gunshot wound, air enters the pleural space and the lung collapses.)

During inhalation, the volume of the thoracic cavity is increased by the contraction of the **diaphragm**, the dome-shaped muscle that forms its floor. When the diaphragm contracts, it moves downward, increasing the volume of the thoracic cavity (FIG. 46-8). The lungs adhere to the walls of the thoracic cavity, so when the volume of the thoracic cavity increases, the space within each lung also increases. The air in the lungs now has more space in which to move about. As a result, air pressure in the lungs falls by 2 or 3 millimeters of mercury (mm Hg) below the air pressure outside the body. Because of this pressure difference, air from the outside rushes in through the respiratory passageways and fills the lungs until the two pressures are equal once again.

During deep or forced inhalation, the *external intercostal muscles* also contract, pulling the rib cage upward and outward.

This action further increases the volume of the thoracic cavity, and more air moves into the lungs.

Exhalation occurs when the diaphragm relaxes. The volume of the thoracic cavity decreases, raising the pressure in the lungs to 2 to 3 mm Hg above atmospheric pressure. The millions of distended air sacs partially deflate and expel the inhaled air. The pressure then returns to normal, and the lung is ready for another inhalation. To summarize: during inhalation, the millions of alveoli fill with air like so many tiny balloons. Then, during exhalation, the air rushes out of the alveoli, partially deflating them.

During forced exhalation, muscles of the abdominal wall and the *internal intercostal muscles* contract, pushing the diaphragm up and the ribs down. This action decreases the volume of the thoracic cavity, pushing air out of the lungs.

Some of the work required to stretch the thorax and the lungs is necessary to stretch their elastic connective tissue. Work is also required to overcome the cohesive force of water molecules associated with the pleural membranes. The forces between the water molecules produce a surface tension that resists stretching.

The work of breathing is reduced by *pulmonary surfactant*, a detergent-like phospholipid mixture secreted by specialized epithelial cells in the lining of the alveoli. Pulmonary surfactant intersperses between the water molecules, reducing their cohesive force. This action markedly reduces the surface tension of the water, prevents the alveoli from collapsing, and reduces the energy required to stretch the lungs. Premature infants often cannot produce enough surfactant, which causes respiratory distress syndrome. In these infants, high surface tension makes it difficult to inflate the lungs, and the alveoli collapse during expiration. Breathing is labored. Respiratory failure as a result of surfactant deficiency is a leading cause of morbidity and mortality in premature infants. Surfactant deficiency can be treated with surfactant replacement therapy in which artificial surfactant is delivered through the trachea.

The quantity of respired air can be measured

The amount of air moved into and out of the lungs with each normal resting breath is called the **tidal volume**. The normal tidal volume is about 500 mL. A great deal of stale air remains in the lungs during normal resting breathing. The volume of air that remains in the lungs at the end of a maximal expiration is the **residual volume** (about 1200 mL).

The **vital capacity** is the maximum amount of air a person can exhale after filling the lungs to the maximum extent (about 4500 mL). Vital capacity is a useful measure of the functional capacity of the lungs.

Gas exchange takes place in the alveoli

The respiratory system delivers oxygen to the alveoli, but if oxygen remained in the lungs, all the other body cells would soon die. The vital link between alveoli and body cells is the circulatory system. Clusters of pulmonary capillaries surround the alveoli, bringing blood close to the alveolar air. Each alveolus serves as a tiny depot from which oxygen diffuses into the blood (FIG. 46-9).

Key Point

Oxygen diffuses through the thin wall of each alveolus and then through the thin walls of the surrounding capillaries to reach the blood. Carbon dioxide diffuses from the blood into the alveoli.

(b) SEM of alveoli and surrounding pulmonary capillaries. The capillary networks are so dense that each alveolus is surrounded by continuously flowing blood.

(c) Color-enhanced TEM of a portion of a capillary and the wall of an alveolus. The dark structure extending through the capillary is part of a red blood cell. Note the very short distance that oxygen must diffuse to get from the air within the alveolus to the red blood cells that transport it to the body tissues.

Figure 46-7 Structure and function of alveoli

Each bronchiole ends in a cluster of alveoli (air sacs). Gases are exchanged between the air in the alveoli and the blood in the capillaries. The lungs contain approximately 500 million alveoli.

CONNECT In what way is the structure of capillaries (discussed in Chapter 44) essential to efficient gas exchange in the alveoli?

(a) Inhalation. The diaphragm contracts, increasing the volume of the thoracic cavity. Air moves into the lungs.

(b) Exhalation. The diaphragm relaxes, decreasing the volume of the thoracic cavity. Air moves out of the lungs.

(c) Forced inhalation. The external intercostal muscles contract, pulling the rib cage upward and outward. This action increases the front-to-back dimension of the chest and correspondingly increases the volume of the thoracic cavity.

(d) Forced exhalation. The internal intercostal muscles contract, pulling the rib cage downward and inward. The volume of the thoracic cavity decreases.

Figure 46-8 Mechanics of breathing

During inhalation and exhalation, the position of the diaphragm and of the external and internal intercostal muscles changes. These changes increase or decrease the volume of the thoracic cavity.

Oxygen molecules efficiently pass by simple diffusion from the alveoli, where they are more concentrated, into the blood in the pulmonary capillaries, where they are less concentrated. At the same time, carbon dioxide moves from the blood, where it is more concentrated, to the alveoli, where it is less concentrated. Each gas diffuses through the single layer of cells lining the alveoli and the single layer of cells lining the capillaries.

Recall that in aerobic respiration, oxygen is the final electron acceptor; it accepts two electrons, which are added to two protons to produce water (see Chapter 8). Inhaled (atmospheric) air contains about 20.9% oxygen, but because oxygen is used during cellular respiration, exhaled (alveolar) air contains only 14% oxygen. Carbon dioxide is produced during aerobic respiration. For this reason, exhaled air contains more than one hundred times as much (5.6%) carbon dioxide as inhaled air (about 0.04% carbon dioxide).

The concentration of oxygen in the cells is lower than in the capillaries entering the tissues, and the concentration of carbon dioxide is higher in the cells than in the capillaries. As blood circulates through capillaries of a tissue such as brain or muscle, oxygen moves by simple diffusion from the blood to the cells, and carbon dioxide moves from the cells into the blood.

The factor that determines the direction and rate of diffusion is the pressure or tension of the particular gas. According to *Dalton's law of partial pressures*, in a mixture of gases, the total pressure of the mixture is the sum of the pressures of the individual gases. Each gas exerts, independently of the others, a **partial pressure**, the same pressure it would exert if it were present alone. At sea level, the barometric pressure (the pressure of Earth's atmosphere) typically supports a column of mercury 760 mm high. Because oxygen makes up about 21% of the atmosphere, oxygen's share of that pressure is $0.21 \times 760 = 160$ mm Hg. Thus, 160 mm Hg is the partial pressure of atmospheric O_2 , abbreviated P_{O_2} . In contrast, the partial pressure of atmospheric CO_2 is 0.23 mm Hg, abbreviated P_{CO_2} .

Fick's law of diffusion explains that the amount of oxygen or carbon dioxide that diffuses across the membrane of an alveolus depends both on the differences in partial pressure on the two sides of the membrane and on the surface area of

Figure 46-9 Gas exchange in the lungs and tissues

Note the differences in partial pressures of oxygen and carbon dioxide before and after gases are exchanged in the tissues.

the membrane. The gas diffuses faster if the difference in pressure or the surface area increases.

Gas exchange takes place in the tissues

The partial pressure of oxygen in arterial blood is about 100 mm Hg. The P_{O_2} in the tissues is still lower, averaging about 40 mm Hg. Consequently, oxygen diffuses out of the capillaries and into the tissues. Not all the oxygen leaves the blood, however. The blood passes through the tissue capillaries too rapidly for equilibrium to be reached. As a result, the partial pressure of oxygen in venous blood returning to the lungs is about 40 mm Hg. Thus, exhaled air has had only part of its oxygen removed, which is a good thing for those in need of mouth-to-mouth resuscitation!

Respiratory pigments increase capacity for oxygen transport

Respiratory pigments greatly increase the quantity of oxygen that blood can transport. These molecules combine reversibly with oxygen. **Hemocyanins** are copper-containing proteins dispersed in the hemolymph of many species of mollusks and arthropods. Without oxygen, these pigments are colorless. When oxygen combines with the copper, hemocyanins are blue.

Hemoglobin and **myoglobin** are the most common respiratory pigments in animals. Hemoglobin is the pigment found in the blood of vertebrates. It is also present in many invertebrate species, including annelids, nematodes, mollusks, and arthropods. In some of these animals, the hemoglobin is dispersed in the plasma rather than confined to blood cells. Recall that myoglobin is a form of hemoglobin found in muscle fibers (see Chapter 40).

In humans and other mammals, inhaled oxygen diffuses out of the alveoli and enters the pulmonary capillaries. Plasma in equilibrium with alveolar air can take up only 0.25 mL of oxygen per 100 mL. However, oxygen diffuses into red blood cells (RBCs) and combines with hemoglobin. The properties of hemoglobin permit whole blood to carry some 20 mL of oxygen per 100 mL. Hemoglobin transports almost 99% of the oxygen. The rest is dissolved in the plasma.

The term *hemoglobin* is actually a general name for a group of related compounds. These compounds consist of an iron–porphyrin, or heme, group bound to a protein known as a *globin*. The protein portion of the molecule varies in size, amino acid composition, and physical properties among various species.

The protein portion of hemoglobin is composed of four peptide chains, typically two alpha and two beta chains, each attached to a heme

(iron–porphyrin) ring (see Fig. 3-23a). An iron atom is bound in the center of each heme ring. Hemoglobin has the remarkable property of forming a weak chemical bond with oxygen. An oxygen molecule can attach to the iron atom in each heme. In the lung (or gill), oxygen diffuses into the RBCs and combines with hemoglobin (Hb) to form **oxyhemoglobin** (HbO_2). When combined with oxygen, hemoglobin is bright red; without oxygen, it appears dark red, imparting a purplish color to venous blood.

Because the chemical bond formed between the oxygen and the hemoglobin is weak, the reaction is readily reversible. As blood circulates through tissues where the oxygen concentration is low, the reaction proceeds to the left. Hemoglobin releases oxygen, which diffuses out of the blood and into the cells of the tissues.

The maximum amount of oxygen that hemoglobin can transport is its **oxygen-carrying capacity**. The *actual* amount of oxygen bound to hemoglobin is the *oxygen content*. The ratio of O_2 content to oxygen-carrying capacity is the *percent O_2 saturation* of the hemoglobin. The percent O_2 saturation is highest in the pulmonary capillaries, where the concentration of oxygen is greatest. In the capillaries of the tissues, where there is less oxygen, oxyhemoglobin dissociates, releasing oxygen. There, the percent saturation of hemoglobin is correspondingly lower.

The *oxygen–hemoglobin dissociation curve* shown in **FIGURE 46-10a** illustrates the relationship between partial pressure

(a) Normal oxygen–hemoglobin dissociation curve. Look at the relationship between the partial pressure of oxygen and the percent O_2 saturation of hemoglobin. Oxygen binds to hemoglobin in the lungs and unloads from hemoglobin in the tissues.

Figure 46-10 Oxygen–hemoglobin dissociation curves

(b) Effect of pH on the oxygen–hemoglobin curve (Bohr effect). The normal pH of human blood is 7.4. Find the location on the horizontal axis where the partial pressure of oxygen is 40, and follow the line up through the curves. Notice that the saturation of hemoglobin with oxygen differs among the three curves, even though the partial pressure of oxygen is the same. Oxygen loading increases at higher pH (7.6). At lower pH (7.2), hemoglobin unloads more oxygen.

of oxygen and percent saturation of hemoglobin. As oxygen concentration increases, there is a progressive increase in the percentage of hemoglobin that is combined with oxygen. The ability of oxygen to combine with hemoglobin and be released from oxyhemoglobin is influenced by several factors in addition to percent O_2 saturation. These factors include pH, carbon dioxide concentration, and temperature.

Carbon dioxide produced in respiring tissue reacts with water in the plasma to form carbonic acid, H_2CO_3 . For this reason, any increase in carbon dioxide concentration also increases the acidity (lowers the pH) of the blood. Oxyhemoglobin unloads oxygen more readily in an acidic environment than in an environment with normal pH. Displacement of the oxygen–hemoglobin dissociation curve by a change in pH is known as the **Bohr effect** (FIG. 46-10b). Lactic acid released from active muscles also lowers blood pH and has a similar effect on the oxygen–hemoglobin dissociation curve: more oxygen is unloaded and available for muscle contraction.

Some carbon dioxide is transported by the hemoglobin molecule. Although carbon dioxide attaches to the hemoglobin molecule in a different way and at a different site than oxygen does, the attachment of a carbon dioxide molecule releases an oxygen molecule from the hemoglobin. This effect of carbon dioxide concentration on the oxygen–hemoglobin dissociation curve is important. In the capillaries of the lungs (or gills in fishes), carbon dioxide concentration is relatively low and oxygen concentration is high, so oxygen combines with a very high percentage of hemoglobin. In the capillaries of the tissues, carbon dioxide concentration is high and oxygen concentration is low, so hemoglobin readily unloads oxygen.

The oxygen and carbon dioxide bound to hemoglobin in RBCs do not contribute to the partial pressures that govern diffusion. Loading and unloading of gases onto hemoglobin depend on partial pressures of the plasma and interstitial fluid (which is determined by the gases dissolved in these fluids).

Carbon dioxide is transported mainly as bicarbonate ions

Blood transports carbon dioxide in three forms. About 10% of carbon dioxide dissolves in plasma. Another 30% enters the RBCs and combines with hemoglobin. Because the bond between the hemoglobin and carbon dioxide is very weak, the reaction is readily reversible. Most carbon dioxide (about 60%) moves through plasma as *bicarbonate ions* (HCO_3^-).

In plasma, carbon dioxide slowly combines with water to form carbonic acid. This reaction proceeds much more rapidly inside RBCs as a result of the action of the enzyme *carbonic anhydrase* (FIG. 46-11). Carbonic acid dissociates, forming hydrogen ions and bicarbonate ions.

Most hydrogen ions released from carbonic acid combine with hemoglobin, which is a very effective buffer. Many of the bicarbonate ions diffuse into the plasma. The action of carbonic anhydrase in the RBCs maintains a diffusion gradient for carbon dioxide to move into and then out of RBCs. As the negatively charged bicarbonate ions move out of RBCs, chloride ions (Cl^-) in the plasma diffuse into the RBCs to replace them, a process known as the *chloride shift*. In the alveolar capillaries, CO_2 diffuses out of the plasma and into the alveoli. As the CO_2 concentration decreases, the reaction sequence just described reverses.

Any condition (such as emphysema) that interferes with the removal of carbon dioxide by the lungs can lead to *respiratory acidosis*. In this situation, carbon dioxide is produced more rapidly than it is excreted by the lungs. As a result, the concentration of carbonic acid in the blood increases. When blood pH falls below 7, the central nervous system becomes depressed, and the individual becomes disoriented. Untreated respiratory acidosis can cause coma and death.

Breathing is regulated by respiratory centers in the brain

Breathing is a rhythmic, involuntary process regulated by **respiratory centers** in the brain stem (see Fig. 46-6). Groups of neurons in the medulla regulate the basic rhythm of breathing. These neurons send a burst of impulses to the diaphragm and external intercostal muscles, which causes them to contract. After several seconds, these neurons become inactive, the muscles relax, and exhalation occurs. Respiratory centers in the pons help control the transition from inspiration to exhalation. These centers can stimulate or inhibit the respiratory centers in the medulla. The cycle of activity and inactivity repeats itself so that at rest you breathe about 14 times per minute. Overdose of certain medications, such as barbiturates, depresses the respiratory centers and may lead to respiratory failure.

The basic rhythm of respiration changes in response to the body's needs. When you are playing a fast game of tennis, you need more oxygen than when you are studying biology. During exercise, the rate of aerobic cellular respiration increases, producing more carbon dioxide. Your body must dispose of this carbon dioxide through increased ventilation.

Carbon dioxide concentration is the most important chemical stimulus for regulating the rate of respiration. Specialized **chemoreceptors** in the medulla and in the walls of the aorta and carotid arteries are sensitive to changes in arterial carbon dioxide concentration. When stimulated, they send impulses to the respiratory centers, which increase breathing rate.

The chemoreceptors in the walls of the aorta, called *aortic bodies*, and those in the walls of the carotid arteries, the *carotid bodies*, are sensitive to changes in hydrogen ion concentration and oxygen concentration as well as to carbon dioxide levels. Recall that an increase in carbon dioxide concentration increases hydrogen ions (from carbonic acid) and lowers blood pH. Even a slight decrease in pH stimulates these chemoreceptors, leading to faster breathing. As the lungs remove carbon dioxide, the hydrogen ion concentration in the blood and other body fluids decreases, and homeostasis is re-established.

Key Point

The enzyme carbonic anhydrase (in red blood cells) converts carbon dioxide to carbonic acid; carbonic acid dissociates, producing hydrogen ions and bicarbonate ions. About 60% of carbon dioxide is transported in the plasma as bicarbonate ions.

(a) In the tissues, carbon dioxide diffuses from cells into the plasma. Most of the carbon dioxide enters red blood cells, where the enzyme carbonic anhydrase rapidly converts it to carbonic acid. Carbonic acid dissociates, producing bicarbonate ions (HCO_3^-) and H^+ . As bicarbonate ions move out into the plasma, chloride ions replace them. Hemoglobin combines with H^+ , preventing a decrease in pH.

(b) In the lungs, carbon dioxide diffuses out of the plasma and into the alveoli. The reactions described in (a) are reversed. Bicarbonate ions diffuse from the plasma into the red blood cells. H^+ released from hemoglobin combines with bicarbonate ions, producing carbonic acid. Carbon dioxide produced from the carbonic acid diffuses out of the blood and into the alveoli.

Figure 46-11 Carbon dioxide transport

PREDICT In what way would diffusion of CO_2 into the red blood cells be affected if the carbonic anhydrase enzyme were inhibited?

Interestingly, oxygen concentration generally does not play an important role in regulating respiration. Only if the partial pressure of oxygen falls markedly do the chemoreceptors in the aorta and carotid arteries become stimulated to send messages to the respiratory centers.

Shallow breathing, which occurs in anxiety and in many respiratory diseases, causes *hypoxia*, a deficiency of oxygen. Even *rapid*, shallow breathing results in hypoxia because we do not clear out the stale air in the airway and ventilate the lungs. Hypoxia causes drowsiness, mental fatigue, headache, and sometimes euphoria. The ability to think and make judgments is impaired, as is the ability to perform tasks requiring coordination.

Although breathing is involuntary, the action of the respiratory centers can be consciously influenced for a short

time by stimulating or inhibiting them. For example, you can inhibit respiration by holding your breath. You cannot hold your breath indefinitely, however, because eventually you feel a strong urge to breathe. Even if you could ignore this urge, you would eventually pass out and resume breathing.

People who have stopped breathing because of drowning, smoke inhalation, electric shock, or cardiac arrest can sometimes be sustained by mouth-to-mouth resuscitation until their own breathing reflexes return. **Cardiopulmonary resuscitation (CPR)** is a method for aiding victims who have suffered respiratory and cardiac arrest. CPR must be started immediately because irreversible brain damage occurs within about 4 minutes of oxygen deprivation. A number of organizations offer training in CPR to the general public. You can

also learn to save a life with Hands-Only CPR. Free online instructional materials, including videos, are provided by the American Heart Association and other organizations.

Hyperventilation reduces carbon dioxide concentration

Underwater swimmers and some Asian pearl divers intentionally *hyperventilate* before going underwater. By making a series of deep inhalations and exhalations, they “blow off” CO_2 , markedly reducing the CO_2 content of the alveolar air and of the blood. *Hyperventilation* allows the divers to remain underwater longer before the urge to breathe becomes irresistible.

When hyperventilation continues for a long period, dizziness and sometimes unconsciousness may result. These responses occur because a certain concentration of carbon dioxide is needed in the blood to maintain normal blood pressure. (This mechanism operates by way of the vasoconstrictor center in the brain, which maintains the muscle tone of blood vessel walls.) Furthermore, if divers hold their breath too long, the low concentration of oxygen may result in unconsciousness and drowning.

High flying or deep diving can disrupt homeostasis

The barometric pressure decreases at progressively higher altitudes. Because the concentration of oxygen in the air remains at 21%, the partial pressure of oxygen decreases along with the barometric pressure. When a person moves to a high altitude, his or her body adjusts over time by producing a greater number of RBCs.

Getting sufficient oxygen from the air becomes an ever-increasing problem as we ascend to progressively higher altitudes. All high-flying jets have airtight cabins pressurized to the equivalent of the barometric pressure at an altitude of about 2000 m (6600 ft). If a jet flying at 11,700 m (more than 38,000 ft) suddenly decompressed, the pilot would lose consciousness in about 30 seconds and become comatose in about 1 minute.

In addition to the problems of hypoxia, a rapid decrease in barometric pressure causes *decompression sickness* (commonly known as the “bends” because those suffering from it bend over in pain). When the barometric pressure drops below the total pressure of all gases dissolved in the blood and other body fluids, the dissolved gases tend to come out of solution and form gas bubbles. A familiar example occurs each time you uncork a bottle of soda, reducing pressure in the bottle. Carbon dioxide is released from solution and bubbles out into the air. In the body, nitrogen has a low solubility in blood and tissues. When it comes out of solution, the bubbles produced may damage tissues and block capillaries, interfering with blood flow. The clinical effects of decompression sickness are pain, dizziness, paralysis, unconsciousness, and even death.

Decompression sickness is more common in scuba diving than in high-altitude flying. As a diver descends, the surrounding pressure increases tremendously at a rate of 1 atmosphere (the atmospheric pressure at sea level, which equals 760 mm Hg) for each 10 m (about 32 ft). To prevent lung collapse, a diver

must be supplied with air under pressure, exposing the lungs to very high alveolar gas pressures.

At sea level an adult human has about 1 L of nitrogen dissolved in the body, with about half in the fat and half in the body fluids. After a diver's body has become saturated with nitrogen at a depth of 100 m (325 ft), the body fluids contain about 10 L of nitrogen. To prevent this nitrogen from rapidly bubbling out of solution and causing decompression sickness, the diver must rise to the surface gradually, with stops at certain levels on the way up. These pauses allow nitrogen to be expelled slowly through the lungs.

Some mammals are adapted for diving

Some air-breathing mammals can spend long periods underwater without coming up for air. Dolphins, whales, seals, and beavers have structural and physiological adaptations that allow them to dive for food or to elude their enemies. With their streamlined bodies and forelimbs modified as fins or flippers, diving mammals perform impressive aquatic feats. The Weddell seal can swim under the ice at a depth of 596 m (1955 ft) for more than an hour without coming up for air. The enormous elephant seal, which measures about 5 m (16 to 18 ft) in length and weighs 2 to 4 tons, can plunge even deeper (FIG. 46-12). A female elephant seal can dive to depths of more than 1500 m (almost 5000 ft) in less than 20 minutes and stay beneath the surface for more than an hour.

Bruce Watkins/Animals Animals

Figure 46-12 Deep diver

Elephant seals, like this northern elephant seal (*Mirounga angustirostris*), may be the deepest divers on Earth. Researchers have recorded their dives at depths of more than 1500 m (almost 5000 ft).

Physiological adaptations, including ways to distribute and store oxygen, permit some mammals to dive deeply and remain underwater for long periods. Turtles and birds that dive depend on oxygen stored in their lungs. However, diving mammals do not take in and store extra air before a dive. In fact, seals exhale before they dive. With less air in their lungs, they are less buoyant. Their lungs collapse at about 50 to 70 m into their dive and then reinflate as they ascend, so their lungs do not function for most of the dive. These adaptations are thought to reduce the chance of decompression sickness because with less air in the lungs there is less nitrogen in the blood to dissolve during the dive.

Seals have about twice the volume of blood, relative to their body weight, as nondiving mammals. Diving mammals also have high concentrations of myoglobin, which stores oxygen in muscles. These animals have up to ten times as much myoglobin as do terrestrial mammals. The very large spleen typical of many diving mammals stores oxygen-rich red blood cells. During a dive, the increased pressure squeezes the spleen, releasing the stored red blood cells into the circulation.

Diving mammals markedly reduce the energy expended in deep diving (more than 200 m) by gliding. Filmed video sequences of diving seals and whales show that they glide most of the way down. Gliding is possible because the animal's buoyancy decreases as the lungs gradually collapse and the amount of air in the lungs is reduced. Gravity then pulls the animal downward.

When a mammal dives to its limit, physiological mechanisms known collectively as the **diving reflex** are activated. Metabolic rate decreases by about 20%, which conserves oxygen. Breathing stops, and bradycardia (slowing of the heart rate) occurs. The heart rate may decrease to one-tenth the normal rate, reducing the body's consumption of oxygen and energy. Blood is redistributed so that the heart and brain receive the greatest share; skin, muscles, digestive organs, and other internal organs can survive with less oxygen, and less blood is directed to these organs while an animal is submerged.

The diving reflex is present to some extent in humans, where it may act as a protective mechanism during birth, when an infant may be deprived of oxygen for several minutes. Cases of near drownings, especially of young children, have been documented in which the victim was submerged for as long as 45 minutes in very cold water before being rescued and resuscitated. Some of these survivors showed no brain damage. The shock of icy water slows heart rate, increases blood pressure, and shunts blood to internal organs of the body that most need oxygen (blood flow in arms and legs decreases). Metabolic rate decreases, so less oxygen is required.

CHECKPOINT 46.3

- What is the sequence of inhaled airflow through the respiratory structures in a mammal?
- What happens in the alveoli? Why does alveolar air differ in composition from atmospheric air? Explain.
- **CONNECT** How does carbon dioxide concentration affect the oxygen–hemoglobin dissociation curve?

- **CONNECT** Imagine that you are playing basketball. How would your breathing be affected? What mechanisms are activated to restore homeostasis?

46.4 Breathing Polluted Air

LEARNING OBJECTIVE

- 7 Describe the defense mechanisms that protect the lungs and describe the effects of polluted air and cigarette smoking on the respiratory system.

Several defense mechanisms protect the delicate lungs from the harmful substances we breathe (**FIG. 46-13**). Hairs in the nostrils, the ciliated mucous lining in the nose and pharynx, and the cilia–mucus elevator of the trachea and bronchi trap foreign particles that enter the body in inspired air. Cilia on epithelial cells lining the human airway have chemoreceptors that sense taste. Researchers have shown that when potentially toxic bitter substances are inhaled, the cilia beat more rapidly. This mechanism appears to remove harmful compounds from the airway.

One of the body's most rapid defense responses to breathing dirty air is **bronchial constriction**. In this process, the bronchial tubes narrow, increasing the chance that inhaled particles will land on the sticky mucous lining. Unfortunately, bronchial constriction narrows the airway. Less air can reach the lungs, decreasing the amount of oxygen available to body cells. Fifteen puffs on a cigarette during a 5-minute period increases airway resistance as much as three times, and this added resistance to breathing lasts more than 30 minutes. Chain-smokers and those who breathe heavily polluted air are in a state of chronic bronchial constriction.

David Nunuk/Science Source

Figure 46-13 Urban air pollution

Industry continues to spew tons of pollutants into the atmosphere. Despite modern technology, air pollution still poses a significant health risk.

The Effects of Smoking

Tobacco use is the leading cause of preventable and premature death in the United States. Cigarette smoking kills more people than alcohol, car accidents, suicide, AIDS, homicide, and illegal drugs combined. An estimated 480,000 people die prematurely each year from smoking or exposure to secondhand smoke. More than 16 million Americans have a serious illness caused by smoking. On average, tobacco smokers die ten years earlier than nonsmokers.¹

Tobacco smoke is by far the most important risk factor for lung cancer, the most common lethal cancer worldwide. It is also associated with many other types of cancer and accounts for at least 30% of all cancer deaths. Tobacco smoke is also an important risk factor for cardiovascular disease, chronic obstructive pulmonary disease (COPD), and many other diseases. Despite these grim facts, 9.3% of high school students and about 20% of adults in the United States continue to smoke cigarettes.

Secondhand tobacco smoke is smoke from a burning cigarette, cigar, or pipe, or smoke that has been exhaled by a smoker. Secondhand smoke contains hundreds of toxic chemical compounds, including about 70 known human carcinogens. It causes the deaths of an estimated 49,000 individuals each year in the United States alone. Millions of children and adults are exposed to secondhand smoke in their homes and workplaces. This exposure causes disease and premature death in children and adults who do not smoke. Babies and children exposed to secondhand smoke are at increased risk for sudden infant death syndrome (SIDS), acute respiratory infections, pneumonia, bronchitis, ear infections, and asthma. In adults, secondhand smoke causes cardiovascular disease and lung cancer. About 60% of *nonsmokers* in the United States have biological symptoms of exposure to secondhand smoke. Laws passed during the past 25 or so years that ban smoking in workplaces and public places and increased awareness of the dangers of secondhand smoke have led to a decrease in exposure.

Nicotine dependence is the most common type of chemical dependence in the United States. Studies indicate that nicotine may be

as addictive as alcohol, cocaine, or heroin. Like cocaine, morphine, and amphetamines, nicotine increases dopamine concentration in the limbic system. This region of the brain helps integrate emotion, and dopamine may facilitate learning an association between the pleasurable effects of the drug and other stimuli, such as the smell of smoke. Nicotine, like cocaine and other abused drugs, causes long-lasting changes in the brain. Cell signaling and other mechanisms underlying drug addiction are very similar to those of learning and memory.

An estimated 70% of smokers (more than 33 million) want to quit, but only a small number each year succeed in quitting permanently. Nicotine replacement with gum, patches, nasal spray, inhalers, or lozenges has been shown to be effective as an aid to smoking cessation, especially when used with behavioral therapy. Certain antidepressants are used to reduce the craving for nicotine. One prescription medication (Chantix) works by blocking nicotine receptors in the brain. It reduces symptoms of nicotine withdrawal and also decreases the pleasurable effects of smoking. The Tips From Former Smokers Campaign is credited with helping thousands of smokers in the United States to quit smoking permanently.

Use of electronic cigarettes (also known as e-cigarettes or electronic nicotine delivery systems) is growing rapidly. Electronic cigarettes are battery-powered devices that provide a heated aerosol containing nicotine. The effects of e-cigarettes have not yet been thoroughly studied. Brands vary in the amounts of nicotine they deliver and in their toxin content. However, they are not “harmless” replacements for cigarettes. Also, many individuals who use e-cigarettes become smokers of traditional cigarettes.

Here are some facts about smoking:

- Almost everyone who takes up smoking in the U.S. is a teenager, and every day nearly 4000 teens smoke their first cigarette. About one-third of these teens will die prematurely from a smoking-related disease. The younger you are when you begin to smoke, the more likely you are to be an adult smoker.
- Smoking shortens the life of an adult male smoker by an average of 13.2 years

and shortens the life of an adult female smoker by an average of 14.5 years.

- If you smoke more than one pack of cigarettes per day, you are about 20 times as likely as a nonsmoker to develop lung cancer. Cigarette smoking causes almost nine out of ten lung cancer deaths.
- If you smoke, you double your chances of dying from cardiovascular disease.
- If you smoke, you are 20 times more likely as a nonsmoker to develop chronic bronchitis and emphysema. About 90% of all deaths from chronic obstructive pulmonary disease are caused by cigarette smoking.
- If you smoke, you have about 5% less oxygen circulating in your blood (because carbon monoxide binds to hemoglobin) than does a nonsmoker.
- If you smoke when you are pregnant, your baby will weigh about 6 ounces less at birth, and there is a higher risk of miscarriage, premature birth (early delivery), stillbirth, and sudden infant death syndrome.
- Infants whose parents smoke have double the risk of contracting pneumonia or bronchitis in their first year of life.
- There is no risk-free level of exposure to secondhand smoke. Nonsmokers who are exposed to secondhand smoke increase their risk of developing heart disease by 25% to 30% and lung cancer by 20% to 30%.
- When smokers quit smoking, their risk of dying from chronic obstructive pulmonary disease, cardiovascular disease, or cancer gradually decreases. (Precise changes in risk depend on the number of years the person smoked, the number of cigarettes smoked per day, the age of starting to smoke, and the number of years since quitting.)
- The direct medical costs of tobacco use in the U.S. amount to more than \$96 billion annually.
- Smokeless tobacco products (snuff, chewing tobacco) are not a safe alternative to tobacco smoking. All forms of these products contain chemicals that cause cancer.

Neither the smallest bronchioles nor the alveoli are equipped with mucus or ciliated cells. Foreign particles that get through other respiratory defenses and find their way into the alveoli may be engulfed by macrophages. The macrophages may then accumulate in the lymph tissue of the lungs. Lung tissues of cigarette smokers and those who work in dirty industries burning fossil fuel contain large blackened areas where carbon particles have been deposited (FIG. 46-14).

Continued insult to the respiratory system results in disease. Chronic bronchitis, pulmonary emphysema, and lung cancer have been linked to cigarette smoking and breathing polluted air. More than 75% of patients with *chronic bronchitis* have a history of heavy cigarette smoking (see *Inquiring About: The Effects of Smoking*). People with chronic bronchitis often develop **pulmonary emphysema**, a disease also most common in cigarette smokers. In this disorder, alveoli lose their

(b) Lungs of a cigarette smoker. The dark spots in the lung tissue are particles of carbon, tar, and other substances that passed through the respiratory defenses and lodged in the lungs.

Figure 46-14 Effects of cigarette smoking

elasticity, and walls between adjacent alveoli are destroyed. The surface area of the lung is so reduced that gas exchange is seriously impaired. Air is not expelled effectively, and stale air accumulates in the lungs.

The emphysema victim struggles for every breath, and still the body does not get enough oxygen. To compensate, the right ventricle of the heart pumps harder and becomes enlarged. Emphysema patients frequently die of heart failure.

Most patients with *chronic obstructive pulmonary disease (COPD)*, a condition characterized by obstructed airflow, have both chronic bronchitis and emphysema. Asthma also contributes to COPD. People with asthma respond to inhaled stimuli with exaggerated bronchial constriction, and the airway is typically inflamed.

Cigarette smoking is also the main cause of *lung cancer*. At least 70 of the 4800 chemical compounds in tobacco smoke cause cancer in animals, including humans. These carcinogenic substances irritate the cells lining the respiratory passages and alter their metabolic balance. Normal cells are transformed into cancer cells, which may multiply rapidly and invade surrounding tissues.

CHECKPOINT 46.4

- What mechanisms does the human respiratory system have for getting rid of inhaled particles?
- **CONNECT** What happens when so much dirty air is inhaled that the respiratory system's defense mechanisms cannot function effectively?

Summary: Focus on Learning Objectives

46.1 Adaptations for Gas Exchange in Air or Water

(page 992)

1 Compare the advantages and disadvantages of air and water as mediums for gas exchange and describe adaptations for gas exchange in air.

- Air contains a higher concentration of molecular oxygen than water, and oxygen diffuses more rapidly through air than through water. Air is less dense and less viscous than water, so less energy is needed to move air over a gas exchange surface.
- Terrestrial animals have adaptations that protect their respiratory surfaces from drying, including location deep in the body. Also, air is humidified as it passes through the moist upper airway.

46.2 Types of Respiratory Surfaces (page 992)

2 Describe the following adaptations for gas exchange: body surface, tracheal tubes, gills, and lungs.

- Small aquatic animals exchange gases by diffusion; they require no specialized respiratory structures. Some invertebrates, including most annelids, and a few vertebrates (many amphibians) exchange gases across the body surface.
- In insects and some other arthropods, air enters a network of **tracheal tubes**, or **tracheae**, through openings, called **spiracles**, along the body surface. Tracheal tubes branch and extend to all regions of the body.
- **Gills** are moist, thin projections of the body surface found mainly in aquatic animals. In chordates, gills are usually internal, located along the edges of the gill slits. In bony fishes, an **operculum** protects the gills. A **countercurrent exchange system** maximizes diffusion of oxygen into the blood and diffusion of carbon dioxide out of blood.
- Animals carry on **ventilation**, the process of actively moving air or water over respiratory surfaces. Terrestrial vertebrates have **lungs** and some means of ventilating them.

- In birds, the lungs have extensions, called *air sacs*, that act as bellows, drawing air into the system. Two cycles of inhalation and exhalation support a one-way flow of air through the lungs. Air from the outside flows into the posterior air sacs, to the lung, through the anterior air sacs, and then out of the body. Gas exchange takes place through the walls of the **parabronchi**, small, open tubes in the lungs. A crosscurrent arrangement, in which blood flow is at right angles to the parabronchi, increases the amount of oxygen that enters the blood.

46.3 The Mammalian Respiratory System (page 997)

3 Trace the passage of oxygen through the human respiratory system from nostrils to alveoli.

- The human respiratory system includes the lungs and a system of airways. Each breath of air passes in sequence through the *nostrils*, *nasal cavities*, **pharynx**, **larynx**, **trachea**, **bronchi**, **bronchioles**, and **alveoli**. Each lung occupies a pleural cavity and is covered with a **pleural membrane**.

4 Summarize the mechanics of breathing in humans and describe gas exchange in the lungs and tissues.

- During breathing, the **diaphragm** contracts, expanding the chest cavity. The membranous walls of the lungs move outward along with the chest walls, lowering pressure within the lungs. Air from outside the body rushes in through the air passageways and fills the lungs until the pressure equals atmospheric pressure.
- **Tidal volume** is the amount of air moved into and out of the lungs with each normal breath. The volume of air that remains in the lungs at the end of a maximal expiration is the **residual volume**. **Vital capacity** is the maximum volume of air that can be exhaled after the lungs fill to the maximum extent.
- Oxygen and carbon dioxide are exchanged between alveoli and blood by diffusion. The pressure of a particular gas determines its direction and rate of diffusion.
- *Dalton's law of partial pressures* explains that in a mixture of gases, the total pressure of the mixture is the sum of the pressures of the individual gases. Thus, each gas in a mixture of gases exerts a **partial pressure**, the same pressure

it would exert if it were present alone. The partial pressure of atmospheric oxygen, P_{O_2} , is 160 mm Hg at sea level.

- According to **Fick's law of diffusion**, the greater the difference in pressure on the two sides of a membrane and the larger the surface area, the faster the gas diffuses across the membrane.

5 Summarize the mechanisms by which oxygen and carbon dioxide are transported in the blood and identify factors that determine the oxygen-hemoglobin dissociation curve.

- **Hemoglobin** is the respiratory pigment in the blood of vertebrates. Almost 99% of the oxygen in human blood is transported as **oxyhemoglobin (HbO_2)**.
- The maximum amount of oxygen that hemoglobin can transport is the **oxygen-carrying capacity**. The actual amount of oxygen bound to hemoglobin is the *oxygen content*. The *percent O_2 saturation*, the ratio of oxygen content to oxygen-carrying capacity, is highest in pulmonary capillaries, where oxygen concentration is greatest.
- The *oxygen-hemoglobin dissociation curve* shows that as oxygen concentration increases, there is a progressive increase in the amount of hemoglobin that combines with oxygen. The curve is affected by pH, temperature, and CO_2 concentration.
- Oxyhemoglobin dissociates more readily as carbon dioxide concentration increases because carbon dioxide combines with water and produces carbonic acid, which lowers the pH. Displacement of the oxygen-hemoglobin dissociation curve by a change in pH is called the **Bohr effect**.
- About 60% of the carbon dioxide in the blood is transported as bicarbonate ions. About 30% combines with hemoglobin, and another 10% is dissolved in plasma.
- *Carbonic anhydrase* catalyzes the production of carbonic acid from carbon dioxide and water. Carbonic acid dissociates, producing bicarbonate ions (HCO_3^-) and hydrogen ions (H^+).
- Hemoglobin combines with H^+ , which buffers the blood. Many bicarbonate ions diffuse from red blood cells into the plasma; they are replaced by Cl^- . This exchange is known as the *chloride shift*.

6 Describe the regulation of breathing in humans and summarize the physiological effects of hyperventilation and of sudden decompression when a diver surfaces too quickly from deep water.

- **Respiratory centers** in the medulla and pons regulate respiration. These centers are stimulated by **chemoreceptors** sensitive to an increase in carbon dioxide concentration. They also respond to an increase in hydrogen ions and to very low oxygen concentration.
- *Hyperventilation* reduces the concentration of carbon dioxide in the alveolar air and in the blood.
- As altitude increases, barometric pressure falls, and less oxygen enters the blood. This situation can lead to *hypoxia*, or oxygen deficiency, which in turn can lead to loss of consciousness and death. Rapid decrease in barometric pressure can also cause *decompression sickness*, especially common among divers who ascend too rapidly from a dive.

- Diving mammals have unusually high concentrations of **myoglobin**, a pigment that stores oxygen, in their muscles. The **diving reflex**, a group of physiological mechanisms that includes a decrease in metabolic rate, is activated when a mammal dives to its limit.

46.4 Breathing Polluted Air (page 1005)

- 7 Describe the defense mechanisms that protect the lungs and describe the effects of polluted air and cigarette smoking on the respiratory system.

- The ciliated mucous lining of the airway traps inhaled particles. Inhaling polluted air results in *bronchial constriction*, increased mucus secretion, damage to ciliated cells, and coughing.
- Breathing polluted air or inhaling cigarette smoke can cause many diseases, including *chronic bronchitis*, *pulmonary emphysema*, and *lung cancer*.

Test Your Understanding

Know and Comprehend

1. Which of the following is a benefit of gas exchange in air compared with gas exchange in water? (a) air has a higher concentration of molecular oxygen (b) oxygen diffuses more slowly in air (c) no energy is required for ventilation (d) moist respiratory surface is not needed (e) air is denser than water
2. Which of the following are accurately matched? (a) bony fish—operculum (b) insect—alveoli (c) bird—spiracles (d) aquatic mammal—gill filaments (e) shark—dermal gills
3. The most efficient vertebrate respiratory system is that of (a) amphibians (b) birds (c) reptiles (d) mammals (e) humans
4. In a bird, the correct sequence for a breath of air is: 1. anterior air sacs 2. posterior air sacs 3. parabronchi 4. alveoli (a) 1, 2, 4 (b) 2, 1, 3 (c) 2, 3, 1 (d) 2, 4, 1 (e) 1, 3, 2
5. Which sequence most accurately describes the flow of air in the human respiratory system? 1. pharynx 2. bronchus 3. trachea 4. larynx 5. alveolus 6. bronchiole (a) 4, 1, 3, 2, 5, 6 (b) 1, 4, 3, 2, 5, 6 (c) 4, 1, 3, 2, 6, 5 (d) 1, 4, 3, 2, 6, 5 (e) 1, 3, 4, 2, 6, 5
6. The amount of air moved in and out of the lungs with each normal resting breath is the (a) vital capacity (b) residual volume (c) vital volume (d) partial pressure (e) tidal volume
7. According to Fick's law of diffusion, a gas will diffuse faster if the (a) surface is reduced (b) difference in pressure is decreased (c) difference in pressure is increased (d) pH is lowered (e) a and c
8. The concentration of which substance is most important in regulating the rate of respiration? (a) chloride ions (b) oxygen (c) bicarbonate ions (d) nitrogen (e) carbon dioxide
9. When a diver ascends too rapidly, (a) bronchial constriction occurs (b) a diving reflex is activated (c) nitrogen rapidly bubbles out of solution in the body fluids (d) nitrogen hypoxia occurs (e) carbon dioxide bubbles damage the alveoli

10. Which of the following is *not* true of the diving reflex? (a) breathing stops (b) the heart slows (c) less blood is distributed to the muscles (d) metabolic rate increases by about 20% (e) energy consumption decreases

Apply and Analyze

11. **VISUALIZE** Draw and label a diagram illustrating the sequence of structures through which inhaled air travels to reach the alveoli.
12. **EVOLUTION LINK** What are the advantages of having millions of alveoli rather than a pair of simple, balloonlike lungs?
13. **INTERPRET DATA** Look at Figure 46-10b. How would strenuous muscle activity affect the oxygen-hemoglobin dissociation curve? (*Hint*: How does muscular activity affect pH? See Chapter 40 if you need to review this concept.)
14. **PREDICT** What problems would be faced by a terrestrial animal having gills instead of lungs?

Evaluate and Synthesize

15. **EVOLUTION LINK** Under what conditions might it be advantageous for a fish to have lungs as well as gills? What function do the "lungs" of modern fishes serve?
16. **EVOLUTION LINK** Aquatic mammals such as whales and dolphins use lungs rather than gills for gas exchange. Propose a hypothesis to explain why.
17. **SCIENCE, TECHNOLOGY, AND SOCIETY** Tobacco smoking is extremely expensive to our society in economic and health costs as well as in human suffering. How would you solve the tobacco smoking problem? How would you specifically target young people?

47 Processing Food and Nutrition

KEY CONCEPTS

- 47.1** Food processing includes ingestion, digestion, absorption, and elimination; many animal adaptations are associated with mode of nutrition.
- 47.2** Various parts of the vertebrate digestive system are specialized to perform specific functions; accessory glands (liver, pancreas, and salivary glands) secrete fluids and enzymes that are important in digestion.
- 47.3** Most animals require the same basic nutrients: carbohydrates, lipids, proteins, vitamins, and minerals.
- 47.4** Basal metabolic rate is the body's cost of metabolic living; energy metabolism is regulated by complex signaling pathways. Both overnutrition and undernutrition can result in malnutrition.

PHOTO: Atlantic wolffish (*Anarhichas lupus*) snatching a sea star (*Asterias rubens*). Also known as the seawolf, this predator hunts hard-shelled prey, such as echinoderms, mollusks, and crustaceans. The Atlantic wolffish, which can weigh up to 18 kg (40 lb), helps control the density and distribution of populations of sea urchins and certain other invertebrates. The wolffish population has decreased drastically as a result of overfishing, unintentional harm by fishermen (bycatch), and habitat damage. Photographed in the North Sea off St Abbs, Berwickshire, Scotland. Nature Picture Library/Alamy Stock Photo

Animals as diverse as sponges and baleen whales feed on food particles suspended in oceans. Giraffes eat leaves, and antelope graze on grasses. Frogs, lions, and some snakes and insects capture other animals. Although their choices of food and feeding mechanisms are diverse, all animals are **heterotrophs**, organisms that must obtain their energy and nourishment from the organic molecules manufactured by other organisms. What they eat, how they obtain food, and how they process and use food are the focus of this chapter.

Nutrients are substances in food that are used as energy sources to power the systems of the body, as ingredients to make compounds needed for metabolic processes, and as building blocks in the growth and repair of tissues. Obtaining nutrients is of such vital importance that both individual organisms and ecosystems are structured around the central theme of **nutrition**, the process of taking in and using food.

An animal's body plan and its lifestyle are adapted to its particular mode of obtaining food—the most effective mode for its survival. For example, the Atlantic wolffish lives on the ocean floor at depths of up to 120 m (400 ft). Its body is adapted for hunting and eating clams, crabs, sea stars, and sea urchins (see photograph). Both its upper and lower jaws have four to six fanglike teeth that stab and tear its prey. Behind these fangs are three rows of teeth that crush the hard shells of its prey. It also has serrated teeth in its throat.

Nutrition has been an important force in human evolution. Through natural selection, the human diet became more varied than the diets of other primates. Humans also became very efficient at obtaining and modifying (e.g., cooking) food. Their higher-quality diet supported the evolution of a larger, more complex brain.

With only slight variations, all animals require the same basic nutrients: carbohydrates, lipids, proteins, vitamins, and minerals. Carbohydrates, lipids, and proteins are used as energy sources. Eating too much of any of these nutrients can result in weight gain, whereas

eating too few nutrients or an unbalanced diet can result in malnutrition and death. **Malnutrition**, or poor nutritional status, results from dietary intake that is either below or above required needs. In human populations both undernutrition (particularly protein deficiency) and obesity (which results from overnutrition) are serious health problems. Food processing and nutrition are active areas of research.

47.1 Nutritional Styles and Adaptations

LEARNING OBJECTIVE

- 1 Describe food processing and modes of nutrition, and compare the digestive systems of a cnidarian (such as *Hydra*), a flatworm, an earthworm, and a vertebrate.

Feeding is the selection, acquisition, and ingestion of food. Most animals have a specialized digestive system that processes the food they eat. **Ingestion** is the process of taking food into the digestive cavity. In many animals, including vertebrates, ingestion includes taking food into the mouth and swallowing it.

Digestion is the process of breaking down food. Because animals eat the macromolecules made by and for other organisms, they must break down these molecules and synthesize new macromolecules for their own needs. For example, we humans cannot incorporate the proteins and other organic compounds from a hamburger directly into our own cells. We must *mechanically digest* the meat and then *chemically digest* it by enzymatic hydrolysis (see Chapter 3). During digestion, complex organic compounds are degraded into smaller molecular components. For example, proteins are broken down into their component amino acids. These amino acids are then used to synthesize proteins tailored for the needs of that individual at that particular time.

Amino acids and other nutrients pass through the lining of the digestive tract and into the blood by **absorption**. Then the circulatory system transports the nutrients to all the cells of the body. Cells use nutrients to synthesize proteins and other organic compounds or as fuel for cellular respiration. Food that is not digested and absorbed is discharged from the body, a process called **egestion** or **elimination**.

Animals are adapted to their mode of nutrition

We can classify animals based on the type of food they typically eat and on how they obtain food (**FIG. 47-1**). Many adaptations have evolved for each type of feeding. For example, the beaks of birds and the teeth of many vertebrates are specialized for cutting, tearing, crushing, or chewing food.

Animals that feed directly on producers are **herbivores**, or **primary consumers**. Most of what an herbivore eats is not efficiently digested and is eliminated from the body, almost unchanged, as waste. Herbivores must therefore eat large quantities of food to obtain the nourishment they need. Many herbivores—grasshoppers, manatees, elephants, and cattle, for example—spend a major part of their lives eating.

Animals cannot digest the cellulose of plant cell walls, and many adaptations have evolved for extracting nutrients from the plant material they eat. Many herbivores, including termites, cows, and horses, have a symbiotic relationship with bacteria, fungi, and other microorganisms that inhabit their digestive tracts. *Ruminants* (cattle, sheep, deer, giraffes) are hooved animals with a stomach divided into four chambers. Symbiotic bacteria and protists living in the first two chambers digest cellulose, splitting some of the molecule into sugars, which are then used by the host and by the bacteria themselves. The bacteria produce fatty acids during their metabolism, some of which are absorbed by the animal and serve as an important energy source.

Solid bits of food clump together to form a cud. The cud is regurgitated into the animal's mouth, where it is mixed with saliva and chewed again. When the cud is reswallowed, the partly digested food is further broken down. Partially digested food passes into the third chamber, where water and minerals are absorbed into the blood. Digestion is completed in the fourth chamber, which corresponds to the stomach of humans and other animals with a single stomach.

Herbivores are sometimes eaten by secondary and higher-level consumers. These **predators** are adapted for capturing and killing prey. Some predators seize their victims and swallow them alive and whole (see Fig. 47-1d). Others paralyze, crush, or shred their prey before ingesting it. Adaptations for this type of feeding include tentacles, claws, fangs, poison glands, and teeth. (Predators, which may also eat one another, are sometimes referred to as *carnivores*.)

Carnivorous mammals have well-developed canine teeth for stabbing their prey during combat. For example, spotted hyenas, which are formidable predators as well as scavengers, have massive jaws that allow them to consume an entire elephant carcass, including bones and hide. Few nutrients are wasted. Meat is more easily digested than plant food, and carnivore digestive tracts are shorter than those of herbivores.

Omnivores, such as pigs, humans, most bears, and some fishes, consume both plants and animals. Earthworms ingest large amounts of soil containing both animal and plant material. The blue whale, which is the largest animal, filters out tiny algae and animals from the water as it swims. Omnivores often have adaptations that help them distinguish among a wide range of smells and tastes and thereby select a variety of foods.

Animals can also be classified according to the mechanisms they use to feed. Many omnivores are **filter feeders** that remove suspended food particles from the water they inhabit. For example, clams and oysters trap suspended food particles in mucus secreted by their gills. Some echinoderms trap food particles along their tentacles, which are coated with mucus. Baleen whales use rows of hard plates (baleen) suspended from the roof of the mouth to filter small crustaceans.

Some animals feed on fluids by piercing and sucking. Mosquitoes have highly adapted structures for piercing skin and sucking blood. Bats that feed on nectar have a long tongue and a reduced number of teeth. Birds that feed on pollen and nectar have long bills and tongues. The shape, size, and curve of the beak may be specialized for feeding on or capturing a particular type of food (see Fig. 1-13).

(a) **Unusual adaptation of an acorn-eating insect.** The impressively long “snout” of the herbivorous acorn weevil (*Curculio*) is adapted both for feeding and for making a hole in the acorn through which it deposits an egg. When it has hatched, the larva feeds on the contents of the acorn seed.

(b) **An herbivorous bear, the giant panda (*Ailuropoda melanoleuca*).** The panda’s large, flat teeth and well-developed jaws and jaw muscles are adaptations for grinding high-fiber plant food. Most bears are omnivores.

(c) **Long-nose butterfly fish (*Forcipiger longirostris*) foraging in coral.** The mouth (on right) of the long-nose butterfly fish is adapted for extracting small worms and crustaceans from crevices in coral reefs. The false eyespot on the fish’s tail confuses its predators.

(d) **Texas rat snake (*Elaphe obsoleta lindheimeri*) feeding on a common anole (*Anolis carolinensis*) near Dallas, Texas.** This subspecies is found in Louisiana and eastern Texas.

Figure 47-1
Adaptations for obtaining and processing food

Deposit feeders, such as earthworms, fiddler crabs, and sea cucumbers, consume nutrients in soil or sediments. For example, earthworms eat their way through the soil, digesting and absorbing organic material.

Some invertebrates have a digestive cavity with a single opening

Sponges, which are very simple invertebrates, obtain food by filtering microscopic organisms from the surrounding water. Individual cells phagocytose the food particles, and digestion is

intracellular within food vacuoles. Wastes are egested into the water that continuously circulates through the sponge body.

Most animals have a digestive cavity. Digestion within a cavity is more efficient than intracellular digestion because digestive enzymes can be released into one confined space. Less surface area is required. Cnidarians (such as hydras and jellyfish) and flatworms have a **gastrovascular cavity**, a central digestive cavity with a single opening. Cnidarians capture small aquatic animals with the help of their stinging cells and tentacles (FIG. 47-2a). The mouth opens into the gastrovascular cavity. Cells lining this digestive cavity secrete enzymes that break down proteins.

(a) Digestive system of a hydra.

(b) Digestive system of a flatworm.

Figure 47-2 Simple invertebrate digestive systems

(a) Hydras and (b) flatworms (planarians) have a gastrovascular cavity, a digestive tract with a single opening that serves as both mouth and anus.

Digestion continues intracellularly within food vacuoles, and digested nutrients diffuse into other cells. Body contractions promote egestion of undigested food particles through the mouth.

Free-living flatworms begin to digest their prey even before ingesting it. They extend the pharynx out through their mouth and secrete digestive enzymes onto their prey (FIG. 47-2b). After it is ingested, the food enters the branched gastrovascular cavity, where enzymes continue to digest it. Cells lining the gastrovascular cavity phagocytose partly digested food fragments, and digestion is completed within food vacuoles. As in cnidarians, the flatworm digestive cavity has only one opening, so undigested wastes are egested through the mouth.

Figure 47-3 Digestive tract with two openings

The earthworm, like most animals, has a complete digestive tract extending from mouth to anus. Various regions of the digestive tract are specialized to perform different food-processing functions.

Most animal digestive systems have two openings

Most invertebrates, and all vertebrates, have a tube-within-a-tube body plan. The body wall forms the outer tube. The inner tube is a digestive tract with two openings, sometimes referred to as a complete digestive system (FIG. 47-3). Food enters through the mouth, and undigested food is eliminated through the anus. The mixing and propulsive movements of the digestive tract are referred to as **motility**. The propulsive activity characteristic of most regions of the digestive tract is **peristalsis**, waves of muscular contraction that push the food in one direction. More food can be taken in while previously eaten food is being digested and absorbed farther down the digestive tract. In a digestive tract with two openings, various regions of the tube are adapted to perform specific functions.

CHECKPOINT 47.1

- **CONNECT** How have predators adapted to their mode of nutrition?
- How does food processing differ in earthworms and flatworms?
- What are the benefits of a digestive tract with two openings?

47.2 The Vertebrate Digestive System

LEARNING OBJECTIVES

- Trace the pathway traveled by an ingested meal through the human digestive system and describe the structure and function of each structure involved.
- Trace the step-by-step digestion of carbohydrate, protein, and lipid.
- Describe the structural adaptations that increase the surface area of the digestive tract.
- Compare lipid absorption with absorption of other nutrients.

Key Point

Various regions of the digestive tract are specialized to perform specific functions. More food can be ingested while the stomach and duodenum are digesting food that was previously swallowed; and food ingested hours earlier is being absorbed.

Figure 47-4 Human digestive system

The human digestive tract is a long, coiled tube extending from mouth to anus. Food passes from the mouth, through the pharynx and esophagus, and into the stomach. After being partially digested in the stomach, food passes into the small intestine. Digestion continues in the first part of the small intestine. Absorption takes place mainly in the small intestine, which consists of the duodenum, jejunum, and ileum. The large intestine absorbs water and minerals. The large intestine includes the cecum, colon, rectum, and anus. Locate the three types of accessory glands: the liver, pancreas, and salivary glands.

PREDICT A surgeon removes the stomach of a cancer patient. What would the surgeon do to ensure that the patient could continue to digest and absorb food?

Various regions of the vertebrate digestive tract are specialized to perform specific functions (FIG. 47-4). Food passes in sequence through the following specialized regions:

mouth → pharynx (throat) → esophagus → stomach → small intestine → large intestine → anus

The liver, pancreas, and salivary glands (in terrestrial vertebrates) are accessory glands that secrete digestive juices into the digestive tract.

The wall of the digestive tract has four layers. Although various regions differ somewhat in structure, the layers are basically similar throughout the digestive tract (FIG. 47-5a). The **mucosa**, which consists of a layer of epithelial tissue and underlying connective tissue, lines the **lumen** (inner space) of the digestive tract. In the stomach and intestine, the mucosa is greatly folded to increase the secreting and absorbing surface.

Surrounding the mucosa is the **submucosa**, a connective tissue layer rich in blood vessels, lymphatic vessels, and nerves.

A **muscle layer**, consisting of two sublayers of smooth muscle, surrounds the submucosa. In the inner sublayer, the muscle fibers are arranged circularly around the digestive tube. In the outer sublayer, the muscle fibers are arranged longitudinally. Below the level of the diaphragm, the outer connective tissue coat of the digestive tract is called the **visceral peritoneum** (per'-ih-tow-nee'-um). By various folds, it is connected to the **parietal peritoneum**, a sheet of connective tissue that lines the walls of the abdominal and pelvic cavities. The visceral and parietal peritonea enclose part of the coelom, the **peritoneal cavity**. Inflammation of the peritoneum, called **peritonitis**, can be very serious because infection can spread along the peritoneum to most of the abdominal organs.

A double fold of peritoneal tissue, called the **mesentery** (mez'-en-ter-ee), fans outward from the parietal peritoneum to the wall of the intestine (FIG. 47-5b). The mesentery is loosely

(a) **Wall of digestive tract.** From inside out, the layers of the wall are the mucosa, submucosa, muscle layer, and visceral peritoneum.

(b) **The mesentery.** The mesentery is a large, double fold of peritoneal tissue. The greater omentum and transverse colon have been lifted to expose the mesentery.

Figure 47-5 Wall of the digestive tract and mesentery

attached to the outer edge of the small intestine, allowing each coil of the intestine to move freely. Until recently, the mesentery was thought to consist of several separate structures. We now know that the mesentery is a continuous structure, extending from the parietal peritoneum to the wall of the intestine. The mesentery extends along most of the length of the intestine. The **greater omentum**, which develops from the mesentery, hangs down over the intestine like a *fatty apron*.

Although described more than 100 years ago, scientists have only recently begun to understand the importance of the mesentery. It has recently been recognized as an organ—the 79th known human organ! Investigators are just beginning to learn about the mesentery's role in health and disease, including cardiovascular disease, obesity, metabolic syndrome, diabetes, colorectal cancer, and Crohn's disease.

(a) **Predator.** The skull of a coyote shows the pointed incisors and canines, adaptations for ripping flesh.

(b) **Herbivore.** Horses and other herbivores have incisors (and sometimes canines) adapted for cutting off bits of vegetation. Canines are absent in some herbivores. The broad, ridged surfaces of the molars are adapted for grinding plant material.

(c) **Omnivore.** The teeth of humans and other omnivores are adapted for chewing a variety of foods.

Figure 47-6 Teeth and diet

An animal's teeth are adapted for its mode of nutrition.

Food processing begins in the mouth

Imagine that you have just taken a big bite of a hamburger in a bun. The mouth is specialized for ingestion and for beginning the digestive process. Mechanical digestion begins as you bite, grind, and chew the meat and bun with your teeth. Unlike the simple, pointed teeth of fish, amphibians, and non-avian reptiles, the teeth of mammals vary in size and shape and are specialized to perform specific functions. The chisel-shaped **incisors** are used for biting and cutting food, whereas the long, pointed **canines** are adapted for piercing prey and tearing food (**FIG. 47-6**). The flattened surfaces of the **premolars** and **molars** are specialized for crushing and grinding.

Each tooth is covered by *enamel*, the hardest substance in the body (**FIG. 47-7**). Most of the tooth consists of *dentin*,

Food is mechanically and enzymatically digested in the stomach

The entrance to the large, muscular **stomach** is normally closed by a ring of muscle at the lower end of the esophagus. When a peristaltic wave passes down the esophagus, the muscle relaxes, and the bolus then enters the stomach (**FIG. 47-9**). When empty, the stomach is collapsed and shaped almost like a hot dog. Folds of the stomach wall, called **rugae**, give the inner lining a wrinkled appearance. As food enters, the rugae gradually smooth out, which expands the capacity of the stomach to more than a liter.

The stomach is lined with a simple, columnar epithelium that secretes large amounts of mucus. Tiny pits mark the entrances to the millions of **gastric glands**, which extend deep into the stomach wall. *Parietal cells* in the gastric glands secrete hydrochloric acid and *intrinsic factor*, a substance needed for adequate absorption of vitamin B₁₂. *Chief cells* in the gastric glands secrete **pepsinogen**, an inactive enzyme precursor. When it comes in contact with the acidic gastric juice in the stomach, pepsinogen is converted to pepsin, the main digestive enzyme of the stomach. **Pepsin** hydrolyzes proteins, converting them to short polypeptides.

Figure 47-7 Tooth structure

which resembles bone in composition and hardness. The *pulp cavity*, which lies beneath the dentin, is a soft connective tissue containing blood vessels, lymph vessels, and nerves.

While food is being mechanically disassembled by the teeth, it is moistened by saliva. As some of the food molecules dissolve, you can taste the food. (Recall from Chapter 43 that taste buds are located on the tongue and other surfaces of the mouth.) Three pairs of **salivary glands** secrete about a liter of saliva into the mouth cavity each day. Saliva contains an enzyme, **salivary amylase**, which begins the chemical digestion of starch into sugar.

The pharynx and esophagus conduct food to the stomach

After being chewed and fashioned into a lump called a **bolus**, the bite of food is swallowed, moving through the **pharynx** into the **esophagus**. The pharynx, or throat, is a muscular tube that serves as the hallway of both the respiratory system and the digestive system. During swallowing, a small flap of tissue, the **epiglottis**, closes the opening to the airway.

Waves of peristalsis sweep the bolus through the pharynx and esophagus toward the stomach (**FIG. 47-8**). Circular muscle fibers in the wall of the esophagus contract around the top of the bolus and push it downward. Almost at the same time, longitudinal muscles around the bottom of the bolus and below it contract, which shortens the tube.

When the body is in an upright position, gravity helps move the food through the esophagus, but gravity is not essential. Astronauts eat in its absence, and even if you are standing on your head, food will reach your stomach.

Figure 47-8 Peristalsis

Key Point

The structure of the stomach is adapted for digesting food; gastric glands in its mucosa secrete digestive juices, and the three layers of muscle in the stomach wall are important in mechanically digesting food.

Figure 47-9 Structure of the stomach

The stomach is adapted for digesting food mechanically and enzymatically.

CONNECT What is the benefit of having lymph nodules within the gastric mucosa?

Several protective mechanisms prevent the gastric juice from digesting the wall of the stomach. Cells of the gastric mucosa secrete alkaline mucus that coats the stomach wall and neutralizes the acidity of the gastric juice along its lining. In addition, the epithelial cells of the lining fit tightly together, preventing gastric juice from leaking between them and into the tissue beneath. If some of the epithelial cells become damaged, they are quickly replaced. In fact, about a half million of these cells are shed and replaced every minute!

Sometimes, the part of the stomach lining is digested, leaving an open sore, or *peptic ulcer*. Such ulcers also occur in the duodenum and sometimes in the lower part of the esophagus. The bacterium *Helicobacter pylori* is the cause of about 80% of peptic ulcers (see Fig. 25-13). *Helicobacter pylori* infects the mucus-secreting cells of the stomach lining, decreasing the protective mucus, which can lead to peptic ulcers or cancer. This type of infection responds to antibiotic therapy.

What changes occur in a bite of hamburger during its 3- to 4-hour stay in the stomach? The stomach churns and chemically degrades the food so that it assumes the consistency of a thick soup; this partially digested food is called *chyme*.

Digestion of the starch in the bun to small polysaccharides and maltose continues until salivary amylase is inactivated by the acidic pH of the stomach. Protein digestion degrades much of the hamburger protein to polypeptides. Over a period of several hours, peristaltic waves release the chyme in spurts through the stomach exit, the *pylorus*, and into the small intestine.

Most enzymatic digestion takes place in the small intestine

Digestion of food is completed in the **small intestine**, and nutrients are absorbed through its wall. The small intestine, which is 5 to 6 m (about 17 ft) in length, has three regions: the **duodenum**, **jejunum**, and **ileum**. Most chemical digestion takes place in the duodenum, the first portion of the small intestine, not in the stomach. Bile from the liver and enzymes from the pancreas are released into the duodenum and act on the chyme. Then enzymes produced by the epithelial cells lining the duodenum catalyze the final steps in the digestion of the major types of nutrients.

The lining of the small intestine appears velvety because of its millions of tiny fingerlike projections, the intestinal

The digestive and absorptive surface area of the small intestine is vastly increased by millions of fingerlike villi; the surface area is further increased by microvilli of the epithelial cells of the villi.

villi (sing., *villus*) (FIG. 47-10). The villi increase the surface area of the small intestine for digestion and absorption of nutrients. The intestinal surface is further expanded by **microvilli**, projections of the plasma membrane of the simple columnar epithelial cells of the villi. About 600 microvilli protrude from the exposed surface of each cell, giving the epithelial lining a fuzzy appearance when viewed with the light microscope.

If the intestinal lining were smooth, like the inside of a water pipe, food would zip right through the intestine, and many valuable nutrients would not be digested or absorbed. Folds in the wall of the intestine, the villi, and microvilli together increase the surface area of the small intestine by about 600 times. If we could unfold and spread out the lining of the small intestine of an adult human, its surface would approximate the size of a tennis court.

Figure 47-11 The liver and pancreas

The gallbladder stores bile from the liver. Note the ducts that conduct bile to the gallbladder and the duodenum. The stomach has been displaced to expose the pancreas, which secretes several digestive enzymes into the duodenum.

The liver secretes bile

The **liver**, the largest internal organ and also one of the most complex organs in the body, lies in the upper-right part of the abdomen just under the diaphragm (**FIG. 47-11**). The liver secretes **bile**, which mechanically digests fats by a detergent-like action (discussed in a later section). Bile consists of water, bile salts, bile pigments, cholesterol, salts, and lecithin (a phospholipid). Because it contains no digestive enzymes, bile does not enzymatically digest

food. The pear-shaped **gallbladder** stores and concentrates bile and releases it into the duodenum as needed.

A single liver cell can carry on more than 500 separate, specialized metabolic activities! The liver performs these vital functions:

1. Secretes bile that mechanically digests fats
2. Helps maintain homeostasis by removing or adding nutrients to the blood
3. Converts excess glucose to glycogen and stores it
4. Converts excess amino acids to fatty acids and urea
5. Stores iron and certain vitamins
6. Detoxifies alcohol and other drugs and poisons

The pancreas secretes digestive enzymes

The **pancreas** is an elongated gland that secretes both digestive enzymes and hormones that help regulate the level of glucose in the blood. The cells that line the pancreatic ducts secrete an alkaline solution rich in bicarbonate ions. This pancreatic juice neutralizes the stomach acid in the duodenum and provides the optimal pH for action of the pancreatic enzymes. Pancreatic enzymes include **trypsin** and *chymotrypsin*, which digest polypeptides to short peptides; *pancreatic lipase*, which degrades fats; *pancreatic amylase*, which breaks down almost all types of complex carbohydrates, except cellulose, to disaccharides; and *ribonuclease* and *deoxyribonuclease*, which split the nucleic acids ribonucleic acid (RNA) and deoxyribonucleic acid (DNA) into free nucleotides.

Nutrients are digested as they move through the digestive tract

Chyme moves through the digestive tract by peristalsis, mixing contractions, and motions of the villi. As nutrients in the chyme move through the small intestine, they come into contact with enzymes that digest them (**TABLE 47-1**).

Table 47-1 Summary of Digestion

	Carbohydrates	Proteins	Lipids
Mouth	Polysaccharides ↓ Salivary amylase Maltose and small polysaccharides		
Stomach	Action continues until acidic pH inactivates salivary amylase	Protein ↓ Pepsin Short polypeptides	
Small intestine	Undigested polysaccharides ↓ Pancreatic amylase Maltose and other disaccharides ↓ Maltase, sucrase, lactase Monosaccharides	Polypeptides ↓ Trypsin, chymotrypsin Short peptides ↓ Carboxypeptidase, peptidases, dipeptidases Amino acids	Glob of fat ↓ Bile salts Emulsified fat droplets ↓ Pancreatic lipase Fatty acids and glycerol

Carbohydrates are digested to monosaccharides

Polysaccharides, such as starch and glycogen, are important components of the food ingested by most animals. The glucose units of these large molecules are connected by glycosidic bonds linking carbon 4 (or 6) of one glucose molecule with carbon 1 of the adjacent glucose molecule. These bonds are hydrolyzed (broken down through the addition of water molecules; see Chapter 3) by *amylases* that digest polysaccharides to the disaccharide maltose. Although amylase can split the α -glycosidic linkages present in starch and glycogen, it cannot split the β -glycosidic linkages present in cellulose (see Figs. 3-9 and 3-10).

Enzymes produced by the cells lining the small intestine break down disaccharides such as maltose to monosaccharides. *Maltase*, for example, splits maltose into two glucose molecules (see Fig. 3-8a). Hydrolysis occurs while the disaccharides are being absorbed through the epithelium of the small intestine.

Proteins are digested to amino acids Several proteolytic enzymes are secreted into the digestive tract. Each enzyme breaks peptide bonds at one or more specific locations in a polypeptide chain. Trypsin, secreted in an inactive form by the pancreas, is activated by an enzyme called *enterokinase*. The trypsin then activates chymotrypsin and carboxypeptidase as well as additional trypsin.

Carboxypeptidase removes amino acids with free terminal carboxyl groups from the end of polypeptide chains. Pepsin, trypsin, and chymotrypsin break certain internal peptide bonds of proteins and polypeptides. *Dipeptidases* released by the duodenum then split the small peptides into amino acids.

Fats are digested to fatty acids and monoacylglycerols Lipids are usually ingested as large masses of triacylglycerols (also called triglycerides; recall from Chapter 3 that a triacylglycerol is a glycerol molecule chemically combined with three fatty acids; see Fig. 3-12b). They are digested mainly within the duodenum by pancreatic lipase. Like many other proteins, lipase is water soluble, but its substrates are not. Thus, the enzyme can attack only the fat molecules at the surface of a mass of fat.

Bile salts act like detergents, reducing the surface tension of fats. Their action, called *emulsification*, breaks large masses of fat into smaller droplets. Emulsification greatly increases the surface area of fat exposed to the action of pancreatic lipase. In this way, bile salts increase the rate of lipid digestion.

Conditions in the intestine are usually not optimal for the complete hydrolysis of lipids to glycerol and fatty acids. Consequently, the products of lipid digestion include monoacylglycerols (monoglycerides) and diacylglycerols (diglycerides) as well as glycerol and fatty acids. Undigested triacylglycerols also remain, some of which are absorbed without digestion.

Nerves and hormones regulate digestion

Most digestive enzymes are produced only when food is present in the digestive tract. Salivary gland secretion is controlled entirely by the nervous system, but secretion of other digestive juices is regulated by both nerves and hormones. The wall of the digestive tract contains dense networks of neurons. This *enteric nervous system* continues to regulate many motor and secretory activities of the digestive system even if sympathetic and parasympathetic nerves to these organs are cut. Many neuropeptides present in the brain are also released by neurons in the digestive tract and help regulate digestion. For example, *substance P* stimulates smooth muscle contraction of the digestive tract, and *enkephalin* inhibits it (see Table 41-2).

Several hormones, including *gastrin*, *secretin*, *cholecystokinin* (CCK), and *glucose-dependent insulinotropic peptide* (GIP), help regulate the digestive system (TABLE 47-2). These hormones are small polypeptides secreted by endocrine cells in the mucosa of certain regions of the digestive tract. Investigators are studying several other messenger peptides that are important in regulating digestive activity.

As an example of the regulation of the digestive system, consider the secretion of gastric juice. Seeing, smelling, tasting, or even thinking about food causes the brain to send neural signals to the gastric glands in the stomach. These signals stimulate these glands to secrete gastric juice. In addition, when food

Table 47-2 Some Hormones That Regulate Digestion				
Hormone	Source	Target Tissue	Actions	Factors That Stimulate Release
Gastrin	Stomach (mucosa)	Stomach (gastric glands)	Stimulates gastric glands to secrete pepsinogen and HCl; stimulates gastric motility	Distention of the stomach by food; certain substances such as partially digested proteins and caffeine
Secretin	Duodenum (mucosa)	Pancreas	Stimulates pancreas to secrete sodium bicarbonate, which neutralizes acid in duodenum	Acidic chyme acting on mucosa of duodenum
		Liver	Stimulates bile secretion	
		Stomach	Inhibits gastric secretion and gastric emptying	
Cholecystokinin (CCK)	Duodenum (mucosa)	Pancreas	Stimulates release of digestive enzymes	Presence of fatty acids and partially digested proteins in duodenum
		Gallbladder	Stimulates emptying of bile	
		Brain	Helps regulate food intake by signaling satiety	
Glucose-dependent insulinotropic peptide (GIP)	Duodenum (mucosa)	Pancreas	Stimulates insulin secretion	Presence of glucose in duodenum

distends the stomach, stretch receptors send neural messages to the medulla. The medulla then sends messages to endocrine cells in the stomach wall that secrete gastrin. After being transported by the circulatory system, gastrin returns to the stomach, where it stimulates the stomach to release gastric juice. Gastrin also stimulates gastric and intestinal motility, and gastric emptying.

Absorption takes place mainly through the villi of the small intestine

Only a few substances—water, simple sugars, salts, alcohol, and certain drugs—are small enough to be absorbed through the stomach wall. Absorption of nutrients is primarily the job of the intestinal villi. As illustrated in Figure 47-10, the wall of a villus is a single layer of epithelial cells. Inside each villus is a network of capillaries and a central lymph vessel, called a **lacteal**.

To reach the blood (or lymph), a nutrient molecule must pass through an epithelial cell lining the intestine and through a cell lining a blood or lymph vessel. Absorption occurs by a combination of simple diffusion, facilitated diffusion, and active transport. Because glucose and amino acids cannot diffuse through the intestinal lining, they must be absorbed by active transport. Absorption of these nutrients is coupled with the active transport of sodium (see Chapter 5). Fructose is absorbed by facilitated diffusion.

Amino acids and glucose are transported directly to the liver by the *hepatic portal vein*. In the liver this vein divides into a vast network of tiny blood sinuses, vessels similar to capillaries. As the nutrient-rich blood moves slowly through the liver, nutrients and certain toxic substances are removed from the circulation.

The products of lipid digestion are absorbed by a different process and different route. After free fatty acids and monoacylglycerols enter an epithelial cell in the intestinal lining, they are reassembled as triacylglycerols in the smooth endoplasmic reticulum. The triacylglycerols, along with absorbed cholesterol and phospholipids, are packaged into protein-covered fat droplets, called **chylomicrons**.

After they are released into the interstitial fluid, chylomicrons enter the lacteal (lymph vessel) of the villus. Chylomicrons are transported in the lymph to the subclavian veins, where the lymph and its contents enter the blood. About 90% of absorbed fat enters the blood circulation in this indirect way. The rest, mainly short-chain fatty acids such as those in butter, are absorbed directly into the blood. After a meal rich in fats, the great number of chylomicrons in the blood may give the plasma a turbid, milky appearance for a few hours. Chylomicrons transport fats to the liver and other tissues.

Most of the nutrients in the chyme are absorbed by the time it reaches the end of the small intestine. What is left (mainly waste) passes through a sphincter, the *ileocecal valve*, into the large intestine.

The large intestine eliminates waste

Undigested material, such as the cellulose of plant foods, along with unabsorbed chyme passes into the **large intestine** (see Fig. 47-4). Although only about 1.3 m (about 4 ft) long, this part of the digestive tract is referred to as “large” because its diameter

is greater than that of the small intestine. The small intestine joins the large intestine about 7 cm (2.8 in.) from the end of the large intestine, forming a blind pouch, the **cecum**. Herbivores such as rabbits have a large, functional cecum that holds food while bacteria digest its cellulose. The *vermiform appendix* projects from the end of the cecum. (Appendicitis is an inflammation of the appendix.) Until recently, the appendix was considered a vestigial organ. Researchers have recently discovered that the appendix plays an important role in immune functions.

From the cecum to the **rectum** (the last portion of the large intestine), the large intestine is known as the **colon**. The regions of the large intestine are the cecum; ascending colon; transverse colon; descending colon; sigmoid colon; rectum; and **anus**, the opening for the elimination of wastes.

As chyme passes slowly through the large intestine, water and sodium are absorbed from it, and it gradually assumes the consistency of normal feces. Members of the intestinal **microbiome** (also referred to as the gut microbiome) that inhabit the large intestine are nourished by the last remnants of the meal. In exchange, certain bacteria of the microbiome produce large amounts of vitamin K and certain B vitamins (biotin, thiamine, and riboflavin) that can be absorbed and used. (The intestinal microbiome is part of the human microbiome, described in Chapter 25.)

Researchers are currently studying the relationship of the intestinal microbiome with many important health issues, including obesity, cancer, and mental health. For example, members of the intestinal microbiome produce a high percentage of the serotonin that the brain uses to regulate mood. Insufficient serotonin in the brain is associated with depression and anxiety. The microbiome also works with the immune system to keep the body healthy. For example, it helps prevent infection from pathogenic organisms (see *Inquiring About: The Human Microbiota: Our Many Symbionts* in Chapter 54).

A distinction should be made between elimination and excretion. *Elimination* is the process of getting rid of digestive wastes, materials that have not been absorbed from the digestive tract and did not participate in metabolic activities. In contrast, *excretion* is the process of getting rid of metabolic wastes, which in mammals is mainly the function of the kidneys and lungs. The large intestine, however, does *excrete* bile pigments, as well as potassium and chloride ions.

When chyme passes through the intestine too rapidly, *defecation* (expulsion of feces) becomes more frequent, and the feces are watery. This condition, called *diarrhea*, may be caused by anxiety, certain foods, or pathogens that irritate the intestinal lining. Prolonged diarrhea results in loss of water and salts and leads to dehydration, which can be a serious condition, especially in infants. *Constipation* results when chyme passes through the intestine too slowly. Because more water than usual is removed from the chyme, the feces may be hard and dry. Constipation is often caused by a diet deficient in fiber. Colorectal cancer occurs in the colon or rectum (FIG. 47-12). In Western countries, colorectal cancer is the second most common cancer, and in the United States, it is the second leading cancer killer. Several factors contribute to the risk of developing colon cancer, including certain genetic factors and family history, smoking, heavy use of alcohol, physical inactivity, and obesity. A diet high in red meat

SPL/Science Source

Figure 47-12 Colon cancer

In this radiographic view of the large intestine, cancer is evident as a mass that projects into the lumen of the colon. (The cancer has been color-enhanced.) The large intestine has been filled with a suspension of barium sulfate, which makes irregularities in the wall visible.

and processed meat and low in fresh fruit, vegetables, poultry, and fish increases the risk. Self-examination and screening are important because they allow early diagnosis. Cancer can be prevented by detecting and removing polyps (benign growths that can become malignant) early. Both men and women should be screened for colorectal cancer beginning at age 50.

CHECKPOINT 47.2

- Imagine that you have just taken a bite of a chicken sandwich. List in sequence the structures through which that food passes in its journey through the digestive system. What happens in each structure?
- CONNECT** How are villi in the small intestine functionally related to rugae in the stomach?
- What are the functions of each of the following: trypsin, bile salts, gastrin, lacteals?
- VISUALIZE** Draw a sketch of the large intestine and label the cecum, transverse colon, descending colon, vermiform appendix, ascending colon, sigmoid colon, and rectum.

47.3 Required Nutrients

LEARNING OBJECTIVES

- Summarize the nutritional requirements for dietary carbohydrates, lipids, and proteins, and trace the fate of glucose, lipids, and amino acids after their absorption.
- Describe the nutritional functions of vitamins, minerals, and phytochemicals.

Adequate amounts of nutrients are necessary for metabolic processes. Animals require carbohydrates, lipids, proteins, vitamins, minerals, and water. Nutritionists are also investigating plant compounds called *phytochemicals* that are important in nutrition. Water is a necessary dietary component because water is the medium in which all the body's biochemical processes take place. Sufficient water must be ingested to replace water lost in urine, sweat, feces, and breath.

Nutritionists continually consider new data and re-examine the *relative* amounts of various types of nutrients recommended for a healthy diet. Current dietary guidelines in the United States suggest that 50% to 60% of our calories should come from carbohydrates, about 30% from fat, and 12% to 20% from protein.

Recall from Chapter 1 that **metabolism** includes all the chemical processes that take place in the body. Metabolism includes anabolic and catabolic processes. **Anabolism** includes the synthetic aspects of metabolism, such as the production of proteins and nucleic acids. **Catabolism** includes breakdown processes, such as hydrolysis. Nutritionists measure the energy value of food in kilocalories, or simply Calories. A Calorie, spelled with a capital C, denotes a **kilocalorie (kcal)**, defined as the amount of heat required to raise the temperature of 1 kilogram of water 1°C.

Carbohydrates provide energy

Sugars and starches are important sources of energy in the human diet. Most carbohydrates are ingested in the form of starch and cellulose, both polysaccharides composed of long chains of glucose subunits. (You may want to review the discussion of carbohydrates in Chapter 3.) Nutritionists refer to *polysaccharides* as *complex carbohydrates*. Foods rich in complex carbohydrates include rice, potatoes, corn, and other cereal grains.

When we eat an excess of carbohydrate-rich food, the liver cells become fully packed with glycogen and convert excess glucose to fatty acids and glycerol. Liver cells convert these compounds to triacylglycerols and send them to the fat deposits of the body for storage.

Refined carbohydrates, such as white bread and white rice, are unhealthy because the refining process removes fiber and many vitamins and minerals. The refining process also produces a form of starch that the digestive system rapidly breaks down to glucose. The resulting rapid increase in glucose concentration in the blood stimulates the pancreas to release a large amount of insulin. This hormone lowers blood glucose level by signaling the liver and muscles to remove glucose from

the blood. When glucose and insulin levels are high, two things happen: triacylglycerol levels increase, and high-density lipoprotein (HDL; the good cholesterol) concentration decreases. These metabolic events can lead to cardiovascular disease and increase the risk of type 2 diabetes (discussed in Chapter 49).

Dietary fiber decreases cholesterol concentration in the blood and is associated with a lower risk for cardiovascular disease and diabetes. *Fiber* is mainly a mixture of cellulose and other indigestible carbohydrates. We obtain dietary fiber by eating fruits, vegetables, and whole grains. The U.S. diet is low in fiber because of low intake of fruits and vegetables and the use of refined flour. Increasing fiber in the diet has a variety of health benefits. For instance, fiber stimulates the feeling of being satisfied (satiety) after food intake and thus is useful in treating obesity.

Lipids provide energy and are used to make biological molecules

Cells use ingested lipids as a source of energy and to make a variety of lipid compounds, including components of cell membranes, steroid hormones, and bile salts. We ingest about 98% of our dietary lipids in the form of triacylglycerols (triglycerides). Triacylglycerols may be saturated—that is, fully loaded with hydrogen atoms—or their fatty acids may be monounsaturated (containing one double bond) or polyunsaturated (containing two or more double bonds).

Three polyunsaturated fatty acids (linoleic, linolenic, and arachidonic acids) are essential fatty acids that humans must obtain from food. Given these and sufficient nonlipid nutrients, the body can make all the lipid compounds (including fats, cholesterol, phospholipids, and prostaglandins) it needs. The average U.S. diet provides far more cholesterol than the recommended daily maximum of 300 mg. High-cholesterol sources include egg yolks, butter, ice cream, and meat.

How are lipids transported? Recall that chylomicrons transport lipids from the intestine to the liver and to other tissues. As chylomicrons circulate in the blood, the enzyme *lipoprotein lipase* breaks down triacylglycerols. The fatty acids and glycerol can then be taken up by the cells. What is left of the chylomicron, a remnant made up mainly of cholesterol and protein, is taken up by the liver.

Liver cells repackage cholesterol and triacylglycerols. These lipids are bound to proteins and transported as large molecular complexes, called **lipoproteins**. Some plasma cholesterol is transported by **high-density lipoproteins**, or **HDLs** (“good” cholesterol), but most is transported by **low-density lipoproteins**, or **LDLs** (“bad” cholesterol). LDLs deliver cholesterol to the cells. For cells to take in LDLs, a protein (apolipoprotein B) on the LDL surface must bind with a protein *LDL receptor* on the plasma membrane (see Fig. 5-22). After binding, the LDL enters the cell, and its cholesterol and other components are used. When cholesterol levels are high, HDLs collect the excess cholesterol and transport it to the liver. HDLs decrease risk for cardiovascular disease.

When needed, stored fats are hydrolyzed to fatty acids and released into the blood. Before cells can use these fatty acids as fuel, they are broken down into smaller compounds and

combined with coenzyme A to form molecules of acetyl coenzyme A (acetyl CoA; **FIG. 47-13**). Acetyl CoA enters the citric acid cycle (see discussion of cellular respiration in Chapter 8). The conversion of fatty acids to acetyl CoA is accomplished in the liver by a process known as *β -oxidation*.

For transport to the cells, acetyl coenzyme A is converted into one of three types of *ketone bodies* (four-carbon ketones). Normally, the level of ketone bodies in the blood is low, but in certain abnormal conditions, such as starvation and diabetes mellitus, fat metabolism is tremendously increased. Ketone bodies are then produced so rapidly that their level in the blood becomes excessive, which may make the blood too acidic to function normally. Such disrupted pH balance can lead to death.

What is the relationship between fat and cholesterol intake and cardiovascular disease? Lipids play a key role in the development of atherosclerosis, a progressive disease in which the arteries become clogged with fatty material (see Chapter 44). Low-density lipoproteins are the main source of the cholesterol that builds up in the walls of arteries. The type of fat consumed—as well as other dietary and lifestyle factors—is important. You can promote a healthy proportion of HDL to LDL by exercising regularly, following a healthy diet, maintaining appropriate body weight (obesity raises LDL and triacylglycerol levels), and by not smoking cigarettes.

In general, animal foods are rich in both saturated fats and cholesterol, whereas most plant foods contain unsaturated fats and no cholesterol. Butter contains mainly saturated fats. Commonly used polyunsaturated vegetable oils are corn,

Figure 47-13 How the body uses fat

The liver converts glycerol and fatty acids to compounds that are used as fuel in cellular respiration. Recall from Chapter 8 that G3P is glyceraldehyde-3-phosphate.

soybean, and safflower oils. Monounsaturated fats raise HDL level, as does stearic acid, the saturated fat in chocolate. Olive, canola, and peanut oils contain large amounts of monounsaturated fats. A few plant oils, including palm oil and coconut oil, are high in saturated fats. Their effects on blood lipids and their role in causing cardiovascular disease are the focus of ongoing investigation. **Omega-3 fatty acids** (found in fish and some plant oils) decrease LDL levels and play other protective roles in decreasing the risk for coronary heart disease.

A diet high in saturated fats and cholesterol increases the cholesterol concentration in the blood by as much as 25%. Because polyunsaturated fats decrease the blood cholesterol level, many people cook with vegetable oils rather than with butter and lard, drink skim milk rather than whole milk, and eat low-fat ice cream. Some use margarine instead of butter. However, during production of many margarines, vegetable oils are partially hydrogenated (some of the carbons accept hydrogen to become fully saturated). During hydrogenation, some double bonds are transformed from a *cis* arrangement to a *trans* arrangement (see Fig. 3-3b), forming *trans fatty acids*; the harder the margarine, the higher the *trans* fatty acid content. Health concerns have been raised because *trans* fatty acids increase LDL cholesterol in the blood and lower HDL. In response there has been a decrease in the use of *trans* fatty acids in commercial products. However, some fast foods, baked goods, and snack foods still contain *trans* fatty acids.

Although some fats, such as *trans* fatty acids and saturated fats, are unhealthy, others, such as omega-3 fatty acids and monounsaturated fat, promote health. The Inuits in Greenland have diets extremely high in fat. However, because their dietary fat is rich in omega-3 fatty acids, they have a low incidence of heart disease.

Proteins serve as enzymes and as structural components of cells

Proteins are essential building blocks of cells, serve as enzymes, and are used to make essential compounds such as receptors, hemoglobin and myosin. Protein consumption is an index of a country's (or an individual's) economic status because high-quality protein tends to be the most expensive and least available of the nutrients. In many parts of the world, protein poverty is one of the most pressing health problems.

Ingested proteins are degraded in the digestive tract to small peptides and amino acids. Of the 20 or so amino acids important in nutrition, approximately 9 (10 in children) cannot be synthesized by humans at all, or at least not in sufficient quantities to meet the body's needs. The diet must provide these **essential amino acids** (see Chapter 3).

Complete proteins, those that contain the most appropriate distribution of amino acids for human nutrition, are found in fish, meat, nuts, eggs, and milk. Some foods, such as gelatin and legumes (soybeans, beans, peas, peanuts), contain a high proportion of protein. However, they either do not contain all the essential amino acids or do not contain them in proper nutritional proportions. Most plant proteins are deficient in one or more essential amino acids. The healthiest sources of protein are fish, chicken, nuts, and legumes.

Amino acids circulating in the blood are taken up by cells and used for the synthesis of proteins. The liver removes excess amino acids from the circulation. Liver cells deaminate amino acids; that is, they remove the amino group (FIG. 47-14). During deamination, ammonia is produced from the amino group. Ammonia, which is toxic at high concentrations, is converted to urea and excreted from the body. The remaining carbon chain of the amino acid (called a *keto acid*) may be converted into carbohydrate or lipid and used as fuel or stored. For this reason, people who eat high-protein diets can gain weight if they eat too much.

Vitamins are organic compounds essential for normal metabolism

Vitamins are organic compounds required in the diet in relatively small amounts for normal biochemical functioning. Many are components of coenzymes (see Chapter 7). Nutritionists divide vitamins into two main groups. *Fat-soluble vitamins* include vitamins A, D, E, and K. *Water-soluble vitamins* are the B and C vitamins. Fruit and vegetables are rich sources of vitamins. TABLE 47-3 provides the sources, functions, and consequences of deficiency for the vitamins.

Figure 47-14 How the body uses protein

The liver plays a central role in protein metabolism. Deamination of amino acids and conversion of the amino groups to urea take place there. In addition, many proteins are synthesized in the liver. Note that you can gain weight on a high-protein diet because excess amino acids can be converted to fat.

Table 47-3 The Vitamins

Vitamins and U.S. RDA	Actions	Effects of Deficiency	Sources
FAT-SOLUBLE VITAMINS			
Vitamin A (retinal)	Converted to retinal; essential for normal vision; essential for normal growth and differentiation of cells; reproduction; immunity	Retarded growth; night blindness; worldwide millions of children are at risk of blindness from vitamin A deficiency; decrease in blood stem cells; increased risk of infections	Liver; fortified milk and dairy products; orange, yellow, and green vegetables and fruit, such as carrots, broccoli, and cantaloupe
Vitamin D (calciferol) Two major forms: vitamin D ₂ is derived mainly from plant foods in diet; vitamin D ₃ is derived from animal foods in diet and synthesis in skin	Promotes calcium and phosphorus absorption from digestive tract; essential to normal growth and maintenance of bone	Weak bones; bone deformities; rickets in children, softening of the bones (osteomalacia) in adults; affects immune function	Fish oils, egg yolk, fortified milk, butter, margarine, salmon; synthesized in the skin through action of sunlight
Vitamin E (tocopherols)	Antioxidant; protects unsaturated fatty acids and cell membranes	Increased catabolism of unsaturated fatty acids so that not enough are available for maintenance of cell membranes; prevention of normal growth; nerve damage	Polyunsaturated plant oils, nuts, leafy greens, whole-grain products
Vitamin K	Synthesis of proteins necessary for blood-clotting; important in bone function	Prolonged blood-clotting time; hemorrhage	Synthesized by bacteria of the intestinal microbiome; leafy greens, legumes
WATER-SOLUBLE VITAMINS			
Vitamin C (ascorbic acid)	Synthesis of collagen, some hormones, and neurotransmitters; antioxidant; important in immune function	Scurvy (wounds heal very slowly, and scars become weak and split open; capillaries become fragile; bone does not grow or heal properly); impaired immunity	Citrus fruit, strawberries, tomatoes, leafy vegetables, cabbage-type vegetables
Thiamine (vitamin B ₁)	Active form is a coenzyme in many enzyme systems; important in carbohydrate and amino acid metabolism	Beriberi (weakened heart muscle, enlarged right side of heart, nervous system and digestive tract disorders; deficiency common in alcoholics)	Liver, meat, fish, yeast, whole-grain or enriched breads, green leafy vegetables; also produced by bacteria of the intestinal microbiome
Riboflavin (vitamin B ₂)	Used to make coenzymes (e.g., FAD) essential in energy metabolism	Dermatitis, inflammation of mouth	Liver, dairy products, meat, green leafy vegetables, whole-grain or enriched breads; also produced by bacteria of the intestinal microbiome
Niacin	Component of important coenzymes (NAD ⁺ and NADP ⁺); essential to energy metabolism	Pellagra (dermatitis, diarrhea, dementia, weakness, fatigue)	Meat, fish, dairy products, nuts, whole-grain or enriched breads
Vitamin B₆ (pyridoxine)	Part of coenzyme needed in amino acid and fatty acid metabolism	Dermatitis, anemia, depression, convulsions	Meat, fish, whole grains, legumes, soy, green leafy vegetables
Pantothenic acid	Component of coenzyme A (important in energy metabolism)	Deficiency rare; sleep disturbances, fatigue	Widespread in foods; meat, eggs, whole grains, legumes
Folate (folic acid)	Coenzyme needed for nucleic acid synthesis and maturation of red blood cells	Anemia; neural tube birth defects; increased risk of cardiovascular disease and certain cancers; deficiency common in alcoholics	Liver, legumes, dark green leafy vegetables, citrus fruit and juices, whole grains
Biotin	Coenzyme important in metabolism	Deficiency uncommon; anemia, dermatitis	Produced by bacteria of the intestinal microbiome; liver, chocolate, egg yolks
Vitamin B₁₂ (cobalamin)	Coenzyme important in DNA synthesis and metabolism; works with folate in production of red blood cells	A type of anemia, fatigue	Liver, meat, fish, dairy products

Health professionals debate the advisability of taking large amounts of certain specific vitamins, such as vitamin C to prevent colds or vitamin E to protect against vascular disease. Some studies suggest that vitamin A (found in yellow and green vegetables) and vitamin C (found in citrus fruits and tomatoes) help protect against certain forms of cancer. We do not yet understand all the biochemical roles

played by vitamins or the interactions among various vitamins and other nutrients. We do know, however, that, like vitamin deficiency, large overdoses of some vitamins can be harmful. Moderate overdoses of the B and C vitamins are excreted in the urine, but surpluses of the fat-soluble vitamins are not easily excreted and can accumulate to harmful levels.

Minerals are inorganic nutrients

Minerals are inorganic nutrients ingested in the form of salts dissolved in food and water (TABLE 47-4). We need certain minerals, including sodium, chloride, potassium, calcium, phosphorus, magnesium, manganese, and sulfur, in amounts of 100 mg or more daily. These nutrients are referred to as *major minerals*. Several others, such as iron, copper, iodide, fluoride, and selenium, are **trace elements**, minerals that we require in minute amounts (less than 100 mg per day).

Minerals are necessary components of body tissues and fluids. Salt content (about 0.9% in plasma) is vital in maintaining the fluid balance of the body, and because salts are lost from the body daily in sweat, urine, and feces, they must be replaced by dietary intake. Sodium chloride (common table salt) is the salt needed in largest quantity in blood and other

body fluids. Deficiency results in dehydration. Iron is the mineral most often deficient in the diet. In fact, iron deficiency is one of the most widespread nutritional problems in the world.

Antioxidants inactivate reactive molecules

Normal cell processes that require oxygen produce **oxidants**, highly reactive molecules such as free radicals, peroxides, and superoxides. **Free radicals**, molecules or ions with one or more unpaired electrons, are also generated by ionizing radiation, alcohol, tobacco smoke, and other forms of air pollution. Oxidants damage DNA, proteins, and unsaturated fatty acids by snatching electrons. Damage to DNA causes mutations that may lead to cancer, and injury to unsaturated fatty

Table 47-4 Some Important Minerals and Their Functions

Mineral	Functions	Sources	Effects of Deficiency; Comments
Calcium	Main mineral of bones and teeth; essential for normal blood clotting, muscle contraction, nerve function, and regulation of cell activities	Milk and other dairy products, fish, green leafy vegetables; bones serve as calcium reservoir	Stunted growth; osteoporosis in adults
Phosphorus	Performs more functions than any other mineral; structural component of bone; component of ATP, DNA, RNA, and phospholipids	Meat, fish, dairy products, cereals	Muscle weakness
Sulfur	Component of many proteins and certain vitamins	High-protein foods such as meat, fish, legumes, nuts	None known
Potassium	Principal positive ion within cells; important in muscle contraction, nerve function, and fluid balance	Meat, milk, fruits, vegetables, grains	Deficiency caused by dehydration; muscle weakness; paralysis; confusion; can cause cardiac arrest
Sodium	Principal positive ion in interstitial fluid; important in fluid balance and acid–base balance; neural transmission	Many foods, table salt; too much ingested in average American diet	Muscle cramps, apathy; excessive amounts may contribute to high blood pressure
Chloride	Principal negative ion of interstitial fluid; important in fluid balance and in acid–base balance; component of hydrochloric acid in stomach	Many foods, table salt	Stunted growth in children; muscle cramps
Magnesium	Needed for normal muscle and nerve function	Nuts, whole grains, legumes, green leafy vegetables, seafood, chocolate	Stunted growth in children; weakness; muscle spasms, confusion
Copper	Component of several enzymes; essential for hemoglobin synthesis	Meats, seafood, whole grains, legumes, seeds	Anemia
Iodine	Component of thyroid hormones (help regulate metabolic rate, growth, and development)	Seafood, iodized salt, vegetables grown in iodine-rich soils	Underactive thyroid gland, goiter (abnormal enlargement of thyroid gland); in children, deficiency affects mental and physical development
Manganese	Activates many enzymes; bone formation	Whole grains, nuts, leafy green vegetables; tea	Poorly absorbed from intestine, but deficiency symptoms rare
Iron	Component of hemoglobin, myoglobin, important respiratory enzymes (cytochromes), and other enzymes essential to oxygen transport and cellular respiration	Good sources: meat (especially liver), fish, nuts, egg yolk, legumes, dried fruit	Iron-deficiency anemia; weakness, fatigue, may impair cognitive function; impaired immunity; mineral most likely to be deficient in diet
Fluoride	Component of bones and teeth; makes teeth resistant to decay	Fluoridated water; seafood; tea	Risk of tooth decay; excess causes tooth mottling
Zinc	Cofactor for at least 70 enzymes; helps regulate synthesis of certain proteins; needed for growth and repair of tissues	Meat, fish, dairy products, whole grains, vegetables	Slowed growth in children; loss of appetite; impaired immune function
Selenium	Antioxidant (cofactor for a peroxidase that protects against oxidation by breaking down peroxides)	Seafood, meat, whole grains	Deficiency is rare

acids can damage cell membranes. Free radicals are thought to contribute to atherosclerosis by causing oxidation of LDL cholesterol. Free radicals also lead to chronic inflammation, rheumatoid arthritis, cardiovascular disease, and aging.

Cells have **antioxidants** that inactivate free radicals and other reactive molecules by donating an electron. Antioxidants in tissues include certain enzymes, such as catalase and peroxidase. Their action requires certain minerals, such as selenium, zinc, manganese, and copper. Vitamins C and E, beta-carotene, and coenzyme Q have strong antioxidant activity. A variety of *phytochemicals* are also potent antioxidants (discussed in next section).

Nutritionists recommend that we increase the antioxidants in our diet by eating fruits, vegetables, and other foods high in antioxidants. Studies indicate that antioxidant compounds decrease inflammation, bacterial and viral activity, and the risk of atherosclerosis, mutations, and cancer.

Phytochemicals play important roles in maintaining health

A diet that includes all the essential nutrients does not provide the same health benefits as one also rich in fruit and vegetables. The missing ingredients are **phytochemicals**, biologically active plant compounds that promote health. Many phytochemicals are antioxidants. For example, *lycopenes*, which are responsible for the red color of tomatoes, are powerful antioxidants. *Flavonoids*, found in cocoa and especially in dark chocolate, are antioxidants that also appear to lower blood pressure, lower cholesterol, and improve cardiovascular health in other ways.

Some important classes of phytochemicals are *carotenoids* (which include vitamin A and lycopene) in deeply pigmented fruits and vegetables such as carrots and tomatoes; *flavonoids* in berries, herbs, vegetables, barley, soy, black and green teas, and cocoa; *isothiocyanates* and *indoles* in broccoli and other cruciferous vegetables; and *organosulfur compounds* in garlic and onions. In Asian countries where diets are low in fat and high in soy and green tea, the incidence of breast, prostate, and colorectal cancer is low.

Diets rich in fruits and vegetables lower the incidence of heart disease and of certain types of cancer. Studies comparing diets in various countries suggest that intake of fruits and vegetables may be more important than differences in dietary fat. Yet nutritionists estimate that in the United States only about 1 person in 10 eats the daily recommended 2 to 6.5 cups of fruits and vegetables a day (the equivalent of 4 to 13 servings).

CHECKPOINT 47.3

- What are the major categories of required nutrients?
- What is the function of glucose? of essential amino acids?
- **CONNECT** How are low-density lipoproteins (LDLs) related to cardiovascular disease?

47.4 Energy Metabolism

LEARNING OBJECTIVES

- 8 Contrast basal metabolic rate with total metabolic rate; write the basic energy equation for maintaining body weight and describe the consequences of altering it in either direction.
- 9 Identify components of the regulatory pathways that regulate food intake and energy homeostasis.
- 10 In general terms, describe the effects of malnutrition, including both overnutrition and undernutrition.

The amount of energy liberated by the body per unit time is a measure of its **metabolic rate**. Much of the energy expended by the body is ultimately converted to heat. Metabolic rate may be expressed either in kilocalories of heat energy expended per day or as a percentage above or below a standard normal level.

The **basal metabolic rate (BMR)** is the rate at which the body releases heat as a result of breaking down fuel molecules. BMR is the body's basic cost of living; that is, it is the rate of energy use during resting conditions. This energy is required to maintain body functions such as heart contraction, breathing, and kidney function. *Total metabolic rate* is the sum of the BMR and the energy used to carry on daily activities. A professional athlete has a greater total metabolic rate than a computer programmer who is inactive most of the day and who does not exercise regularly.

An average-sized man who does not exercise and who sits at a desk all day expends about 2100 kcal daily (women expend less energy). If the food the individual eats each day also contains about the same number of kilocalories, the body will be in a state of energy balance; that is, energy input will equal energy output. This concept is important because body weight remains constant when

$$\text{energy input} = \text{energy output}$$

When people take in less energy in food than they expend in daily activity, the body burns stored fat, and they lose weight. In this case,

$$\text{energy input} < \text{energy output}$$

When people take in more energy in food than they expend in daily activity, they gain weight. In this case,

$$\text{energy input} > \text{energy output}$$

Body mass index (BMI), used worldwide as a measure of body size, is an index of weight in relation to height. It is calculated by dividing the square of a person's weight (in kilograms) by height (in meters). The equivalent in the United States is 4.89 times the weight (in pounds) divided by the square of the height (in feet). An adult with a BMI between 18.5 and 24.9 typically has a healthy weight. Although it is still widely used, BMI is no longer considered a valid measure of obesity because it does not consider important factors such as differences in body composition between males and females, between the average adult and a muscular athlete, or among various races.

Energy metabolism is regulated by complex signaling

The hypothalamus regulates energy metabolism and food intake. Biologists have identified signaling molecules that form complex pathways involving the hypothalamus, digestive system, and adipose tissue. Several appetite regulators, including a family of peptides, signal us to eat or to stop eating. For example, when the stomach is empty, it secretes the peptide hormone **ghrelin** (grel[']-in), which stimulates appetite. Ghrelin stimulates a set of neurons in the hypothalamus to produce the appetite-stimulating neurotransmitter **neuropeptide Y (NPY)**.

Several compounds send “stop eating” signals following a meal. The gastrointestinal tract releases peptides that signal satiety and suppress food intake. For example, **peptide YY**, secreted by the small and large intestine, signals the hypothalamus to stop secreting NPY. The decrease in NPY slows gastric emptying, suppressing appetite. **Cholecystokinin (CCK)**, released by the duodenum, signals satiety and suppresses appetite. After a meal, the pancreas rapidly releases pancreatic polypeptide (PP), which stays elevated for about 5 hours. PP also appears to signal satiety.

Another set of neurons in the hypothalamus release **melanocortins**, which suppress appetite, resulting in decreased food intake and weight loss. NPY and melanocortins also act on other parts of the brain that regulate food intake.

Fat cells in adipose tissue secrete hormones called **adipokines** that are critical in regulating energy metabolism. **Leptin** (from the Greek word *leptos*, “thin”) is an adipokine that helps regulate normal body weight. Leptin signals the hypothalamus about the status of energy stores in adipose tissue. As more fat is stored, more leptin is released. Leptin both slows the release of NPY, which stimulates appetite, and stimulates the release of melanocortins, which decrease appetite.

Another important molecular player in the regulation of energy metabolism is **insulin**. This pancreatic hormone is secreted when the concentration of glucose and other nutrients increases after we eat. Insulin stimulates cells, especially liver, muscle, and fat cells, to take in glucose from the blood and use or store it. The actions of insulin inhibit the hypothalamus from secreting NPY. Thus, insulin inhibits further food intake.

The hypothalamus integrates input from these (and other) signaling molecules with other information, such as the concentration of nutrients circulating in the blood. The brain then sends signals that adjust feeding behavior and metabolism so that homeostasis of stored fat and fuel metabolism is maintained. When food is available and energy stores are adequate, energy use increases, fat stores are mobilized, and food (energy) intake is inhibited. Glucose production in the liver is also inhibited.

In contrast, when food intake is low, as during dieting or starvation, the hypothalamus increases secretion of neuropeptide Y. Appetite increases and metabolism slows, two actions that help restore energy homeostasis. The regulation of food intake and energy metabolism continues to be an important focus of research.

Obesity is a serious nutritional problem

Overnutrition causes **obesity**, the excess accumulation of body fat. More than 65% of U.S. adults are overweight, and

more than 35% of U.S. adults (more than 78 million) are obese. An estimated 32% of U.S. children and adolescents (2 to 19 years old) are overweight.

Obesity is a serious form of malnutrition that has become a problem of epidemic proportions in affluent societies. The World Health Organization considers obesity to be one of the most important global health problems, and the American Medical Association now considers obesity a disease. Obesity contributes to 1 in 5 deaths annually in the United States and is the second leading preventable cause of death (second only to smoking). It is a major risk factor for heart disease, diabetes mellitus, certain types of cancer (including breast and colon cancers), hypertension, osteoarthritis, and liver and gallbladder diseases. In the well-known Framingham study of more than 2000 men, those who were 20% overweight had a significantly higher mortality rate from all causes than those who were not overweight.

Each of us appears to have a **set point**, or steady state, around which body weight is regulated. Dieting can be difficult because when weight decreases below an individual's set point, energy-conserving mechanisms are activated, causing energy expenditure to decrease.

Many factors affect weight In addition to the array of signaling molecules that affect energy metabolism and body weight, researchers have identified several gene mutations that affect food intake and energy homeostasis. For example, the normal *ob* gene product is leptin. Mice with a mutated allele at the *ob* locus become grossly obese. When researchers inject leptin into grossly obese mice, the appetites of the mice decrease and their energy use increases. They lose weight, mainly from loss of body fat (**FIG. 47-15**). Unfortunately, most obese humans are resistant to the actions of leptin.

The number of fat cells in the adult is apparently determined mainly by the amount of fat stored during infancy and childhood. When we are overfed early in life, abnormally large numbers of fat cells are produced. Later in life, these fat cells may be fully stocked with excess lipids or may shrink in size, but they are always there. People with such increased numbers of fat cells are thought to be at greater risk for obesity than are those with normal numbers.

Figure 47-15 Effect of leptin

Mutant *ob* mice before (*left*) and after (*right*) treatment with leptin.

Eating activates the dopamine reward circuit in the brain. (Recall that this circuit is also activated in drug addiction.) The amount of dopamine released corresponds to the intensity of pleasure experienced by eating the food. High-calorie foods rich in fats and sugars strongly stimulate the reward system. These foods also stimulate regions of the brain to produce endorphins. In some people, the pleasurable feelings apparently overpower leptin, insulin, and other hormones that normally interact to suppress appetite and inhibit overeating. As an individual gains weight, more insulin and leptin are released. However, the body apparently develops tolerance to these hormones. As with alcohol, cocaine, and other addictive drugs, the more food the addicted individual consumes, the harder it is to satisfy the craving. One hypothesis holds that some obese individuals may have an underactive dopamine reward system. They overeat to compensate and develop a food addiction in the process.

Although some factors involved in obesity are inherited, behavior is critically important. High-calorie diets, overeating, and underexercising lead to obesity, and psychosocial factors influence these behaviors. A sedentary lifestyle combined with the ready availability of high-energy foods contributes to the problem. One researcher cleverly described the roots of the obesity problem as the combination of “computer chips and potato chips.” For every 9.3 kcal of excess food taken into the body, about 1 g of fat is stored. (An excess of about 140 kcal, less than a typical candy bar, per day for one month results in a 1-lb weight gain.)

Researchers have identified targets for obesity treatment As researchers discover the genetic and biochemical mechanisms that regulate energy metabolism, they provide potential targets for the development of pharmacological treatments for obesity. The following are among the many targets for drug action that are the focus of research: (1) reduce appetite so that food intake is decreased, (2) block absorption of fat, (3) uncouple metabolism from energy production so that food is dissipated as heat (see *Inquiring About: Electron Transport and Heat* in Chapter 8), and (4) block receptors for molecules that send signals leading to increased energy storage.

Undernutrition can cause serious health problems

Billions of people do not have enough to eat or do not eat a balanced diet. Individuals suffering from *undernutrition* are malnourished. Essential amino acids, iron, calcium, iodine, zinc, and vitamin A are nutrients commonly deficient in the diet. Malnutrition results in poor health and lowered resistance to disease.

Worldwide, more than two billion people suffer from nutritional deficiencies. According to the World Health Organization, more than one-third of the world's children suffer from malnutrition. One half of children (age 6 months to 5 years) have nutritional deficiencies. Inadequate amounts of protein and other essential nutrients severely affect physical growth and mental development. Because children suffering from malnutrition cannot manufacture antibodies (which are proteins) or cells needed to fight infection, they often die

P. Pitter/United Nations Food and Agricultural Organization

Figure 47-16 Protein deficiency

Millions of children suffer from kwashiorkor, a disease caused by severe protein deficiency. Note the characteristic swollen belly, which results from fluid imbalance.

from infectious diseases. Globally, malnutrition is the leading cause of death among children.

In young children severe malnutrition results in the condition known as *kwashiorkor*. This Ashanti (West African) word means “first-second” and refers to the situation in which a first child is displaced from its mother's breast when a younger sibling is born. The older child is then given a diet of starchy cereal or cassava that is deficient in protein. Growth becomes stunted, muscles are wasted, and edema develops (as displayed by a swollen belly); the child is anemic and suffers from apathy and impaired metabolism (FIG. 47-16). Without essential amino acids, digestive enzymes cannot be manufactured, so what little protein is ingested cannot be digested. Recent studies suggest that certain gut bacteria may increase the risk for kwashiorkor among malnourished children. In the future, antibiotics may play a role in treatment and recovery.

CHECKPOINT 47.4

- **VISUALIZE** Write an equation to describe energy balance and explain what happens when the equation is altered in either direction.
- What is body mass index (BMI)?
- **CONNECT** How do melanocortins, neuropeptides Y (NPY), ghrelin, and leptin function to maintain energy balance?

Summary: Focus on Learning Objectives

47.1 Nutritional Styles and Adaptations (page 1011)

1 Describe food processing and modes of nutrition, and compare the digestive systems of a cnidarian (such as *Hydra*), a flatworm, an earthworm, and a vertebrate.

- **Nutrition** is the process of taking in and using food. *Feeding* is the selection, acquisition, and **ingestion** of food, that is, taking food into the body. **Digestion** is the process of breaking down food mechanically and chemically. Nutrients pass through the lining of the digestive tract and into the blood by **absorption**. Food that is not digested and absorbed is discharged from the body by *egestion* or **elimination**.
- **Herbivores**, or **primary consumers**, are adapted to feed directly on producers. **Predators** are secondary and higher level consumers adapted for capturing and killing prey. **Omnivores** consume both plants and animals.
- In cnidarians and flatworms, food is digested in the **gastrovascular cavity**. This cavity has a single opening that serves as both mouth and anus. In more complex invertebrates and in all vertebrates, the digestive tract is a complete tube with an opening at each end. Digestion takes place as food passes through the tube. Various parts of the digestive tract are specialized to perform specific functions.

47.2 The Vertebrate Digestive System (page 1013)

2 Trace the pathway traveled by an ingested meal through the human digestive system and describe the structure and function of each structure involved.

- Mechanical and enzymatic digestion of carbohydrates begins in the mouth. Mammalian teeth include **incisors**, which are adapted for biting and cutting food; **canines** adapted for tearing food; and **premolars** and **molars** adapted for crushing and grinding. Three pairs of **salivary glands** secrete saliva, which contains the enzyme **salivary amylase** that digests starch.
- As food is swallowed, it is propelled through the **pharynx** and **esophagus**. A **bolus** of food is moved along through the digestive tract by **peristalsis**, waves of muscular contraction that push food along.
- In the **stomach** food is mechanically digested by vigorous churning, and proteins are enzymatically digested by the action of **pepsin** in the gastric juice. **Rugae** are folds in the stomach wall that expand as the stomach fills with food. **Gastric glands** secrete hydrochloric acid and **pepsinogen**, the precursor of pepsin.
- After several hours, a soup of partly digested food, called *chyme*, leaves the stomach through the *pylorus* and enters the **small intestine** in spurts. Most enzymatic digestion takes place in the **duodenum**, which produces several digestive enzymes and receives secretions from the liver and pancreas.
- The **liver** produces **bile**, which emulsifies fats. The **pancreas** releases enzymes that digest carbohydrate, lipid, and protein as well as RNA and DNA. *Pancreatic amylase* digests complex carbohydrates. *Pancreatic lipase* degrades fats, and **trypsin** and *chymotrypsin* digest polypeptides to small peptides.
- The **large intestine**, which consists of the **cecum**, **colon**, **rectum**, and **anus**, is responsible for eliminating undigested wastes. Bacteria that are part of the intestinal **microbiome**

produce vitamin K and certain B vitamins, and have immune functions.

3 Trace the step-by-step digestion of carbohydrate, protein, and lipid.

- Nutrients in chyme are enzymatically digested as they move through the digestive tract. Polysaccharides are digested to the disaccharide maltose by salivary and pancreatic amylases. *Maltase* in the small intestine splits maltose into glucose, the main product of carbohydrate digestion.
- Proteins are split by pepsin in the stomach and by proteolytic enzymes in the pancreatic juice. *Dipeptidases* split small peptides to amino acids.
- Lipids are emulsified by bile salts and then hydrolyzed by pancreatic lipase.

4 Describe the structural adaptations that increase the surface area of the digestive tract.

- The surface area of the small intestine is greatly expanded by folds in its wall; by the intestinal **villi**, elongated projections of the mucosa; and by **microvilli**, projections of the plasma membrane of the epithelial cells of the villi.

5 Compare lipid absorption with absorption of other nutrients.

- Nutrients are absorbed through the thin walls of intestinal villi. The *hepatic portal vein* transports amino acids and glucose to the liver.
- Fatty acids and monoacylglycerols enter epithelial cells in the intestinal lining, where they are reassembled into triacylglycerols. They are packaged into **chylomicrons**, droplets that also contain cholesterol and phospholipids and are covered with a protein coat. The lymphatic system transports chylomicrons to the blood circulation.

47.3 Required Nutrients (page 1022)

6 Summarize the nutritional requirements for dietary carbohydrates, lipids, and proteins, and trace the fate of glucose, lipids, and amino acids after their absorption.

- Most carbohydrates are ingested in the form of polysaccharides: starch and cellulose. Polysaccharides are referred to as *complex carbohydrates*. *Fiber* is mainly a mixture of cellulose and other indigestible carbohydrates. Carbohydrates are used mainly as an energy source. Glucose concentration in the blood is carefully regulated. Excess glucose is stored as glycogen and can also be converted to fat.
- Lipids are used to provide energy, to form components of cell membranes, and to synthesize steroid hormones and other lipid substances. Most lipids are ingested in the form of triacylglycerols. Fatty acids are converted to molecules of acetyl coenzyme A, which enter the citric acid cycle. Excess fatty acids are converted to triacylglycerol and stored as fat.
- Lipids are transported as large molecular complexes called **lipoproteins**. **Low-density lipoproteins (LDLs)** deliver cholesterol to the cells. **High-density lipoproteins (HDLs)** collect excess cholesterol and transport it to the liver.
- Proteins serve as enzymes and are essential structural components of cells. The best distribution of **essential amino acids** is found in the complete proteins of animal foods. Excess amino acids are deaminated by liver cells. Amino groups are converted to urea and excreted in urine; the remaining keto acids are converted to

carbohydrate and used as fuel or are converted to lipid and stored in fat cells.

7 Describe the nutritional functions of vitamins, minerals, and phytochemicals.

- **Vitamins** are organic compounds required in small amounts for many biochemical processes. Many serve as components of coenzymes. *Fat-soluble vitamins* include vitamins A, D, E, and K. *Water-soluble vitamins* are the B and C vitamins.
- **Minerals** are inorganic nutrients ingested as salts dissolved in food and water. **Trace elements** are minerals required in amounts less than 100 mg per day.
- **Phytochemicals** are plant compounds that promote health. Many phytochemicals are **antioxidants** that destroy **oxidants**, reactive molecules such as **free radicals**. Oxidants damage DNA, proteins, and unsaturated fatty acids by snatching electrons.

47.4 Energy Metabolism (page 1027)

8 Contrast basal metabolic rate with total metabolic rate; write the basic energy equation for maintaining body weight and describe the consequences of altering it in either direction.

- **Basal metabolic rate (BMR)** is the body's cost of metabolic living. *Total metabolic rate* is the BMR plus the energy used to carry on daily activities.
- When energy (kilocalories) input equals energy output, body weight remains constant. When energy output is greater than energy input, body weight decreases. When energy input exceeds energy output, body weight increases.

9 Identify components of the regulatory pathways that regulate food intake and energy homeostasis.

- The hypothalamus, digestive system, and adipose tissue release signaling molecules that help regulate food intake and energy metabolism.
- When empty, the stomach secretes the hormone **ghrelin**, which stimulates appetite. Ghrelin also stimulates the hypothalamus to release **neuropeptide Y (NPY)**, which stimulates appetite.
- After a meal, the intestine secretes **peptide YY** and **cholecystokinin (CCK)**, which signal satiety and decrease appetite. The hypothalamus releases **melanocortins**, which also suppress appetite.
- Adipose tissue secretes **adipokines** that are important in regulating energy metabolism. The adipokine **leptin** signals the brain about the status of energy stores in adipose tissue. Leptin and the pancreatic hormone **insulin** inhibit food intake.

10 In general terms, describe the effects of malnutrition, including both overnutrition and undernutrition.

- In **obesity**, an excess amount of fat accumulates in adipose tissues. Obesity is a major risk factor for several major disorders, including heart disease and diabetes mellitus. A person gains weight by taking in more energy, in the form of kilocalories, than is expended in activity.
- Undernutrition can be caused by not eating enough food or by not eating a balanced diet. Nutrients commonly deficient in the diet include essential amino acids, iron, calcium, iodine, zinc, and vitamin A. Malnourishment prevents normal physical and mental development. In severe malnutrition, death often results from infectious disease, and in children, by conditions such as *kwashiorkor*.

Test Your Understanding

Know and Comprehend

1. Teeth adapted for crushing and grinding are (a) incisors (b) canines (c) premolars and molars (d) incisors and premolars (e) canines and molars
2. The layer of tissue that lines the lumen of the digestive tract is the (a) muscle layer (b) visceral peritoneum (c) parietal peritoneum (d) mucosa (e) submucosa
3. Which of the following are accessory digestive glands? (a) salivary glands (b) pancreas (c) liver (d) a, b, and c (e) a and b
4. Arrange the following into the correct sequence. 1. stomach 2. esophagus 3. pharynx 4. small intestine 5. colon (a) 2, 3, 1, 4, 5 (b) 3, 2, 1, 5, 4 (c) 3, 2, 5, 1, 4 (d) 2, 3, 1, 5, 4 (e) 3, 2, 1, 4, 5
5. Which sequence most accurately describes the digestion of protein? 1. small peptides 2. amino acid 3. protein 4. polypeptide 5. glycerol (a) 4, 3, 1, 2 (b) 3, 4, 1, 2 (c) 3, 4, 1, 5 (d) 4, 3, 5, 1, 2 (e) 2, 1, 4, 5
6. The surface area of the small intestine is increased by (a) folds in its wall (b) villi (c) microvilli (d) a, b, and c (e) a and b
7. Lipids are transported from the intestine to the liver by (a) chylomicrons (b) HDLs (c) LDLs (d) glycerol transporters (e) leptin
8. Most vitamins are (a) inorganic compounds (b) components of coenzymes (c) used as fuel (d) electrolytes (e) required by herbivores and carnivores but not omnivores
9. When energy input is greater than energy output, (a) weight loss occurs (b) weight remains stable (c) weight

gain occurs (d) leptin secretion is inhibited (e) the *ob* gene is deactivated

10. A hormone that stimulates gastric glands to secrete pepsinogen is (a) secretin (b) GIP (c) gastrin (d) cholecystokinin (CCK) (e) Peptide YY

Apply and Analyze

11. **VISUALIZE** Sketch a small area of the lining of the small intestine. Label intestinal glands, lacteal, capillary network of villus, and epithelial cells of villus.
12. Design an experiment to test the hypothesis that the B vitamin pyridoxine is an essential nutrient in mice.

48 Osmoregulation and Disposal of Metabolic Wastes

KEY CONCEPTS

- 48.1** Osmoregulation is the process by which animals regulate the concentration of water and salts in the body, allowing them to maintain their body fluids within homeostatic limits.
- 48.2** During metabolism, most animals produce water, carbon dioxide, and nitrogenous wastes, including ammonia, uric acid, and urea.
- 48.3** Many invertebrates have nephridial organs that carry on osmoregulation and excretion; insects and spiders have Malpighian tubules that excrete metabolic wastes and conserve water.
- 48.4** Freshwater, marine, and terrestrial animals have different adaptations for osmoregulation that meet the challenges of these diverse environments.
- 48.5** The vertebrate kidney maintains water and electrolyte balance and excretes metabolic wastes; the nephron is the functional unit of the vertebrate kidney. Several hormones interact to regulate kidney function.

PHOTO: Most terrestrial animals inhabit areas near water sources. Zebras, giraffes, and a variety of antelopes drink at a waterhole in Etosha National Park, Namibia. Clem Haagner/Science Source

Water, the most abundant molecule both in the cell and on Earth's surface, shapes life and is a critical factor in the distribution of organisms on our planet. Most animals need a dependable source of water with which to replenish their body fluids (see photograph). For this reason, animals often inhabit areas near water sources.

Ions are dissolved in water, the medium in which most metabolic reactions take place. The volume and ionic composition of an animal's body fluids must be maintained within homeostatic limits. Through natural selection, a variety of homeostatic mechanisms have evolved that regulate the volume and composition of fluids in the internal environment.

Many small animals live in the ocean and get their food and oxygen directly from the sea water that surrounds them; they release waste products into the sea water. In larger animals and in most terrestrial animals, an *internal* sea of fluid bathes the cells. Terrestrial animals have a continuous need to conserve water. Water loss from the body must be carefully regulated, and water lost must be replaced. Water is taken in with food and drink, and it is also produced in metabolic reactions.

Two processes that help maintain fluid and electrolyte (salt) homeostasis in animals are *osmoregulation* and *excretion*, the disposal of metabolic wastes. In this chapter we discuss these processes in both invertebrates and vertebrates inhabiting various environments. Then we focus on the structure and functions of the mammalian kidney. We end the chapter with a description of the hormones that regulate kidney function.

48.1 Maintaining Fluid and Electrolyte Balance

LEARNING OBJECTIVE

- 1 Describe how the processes of *osmoregulation* and *excretion* contribute to fluid and electrolyte homeostasis.

Intracellular fluid, the fluid within cells, accounts for most of the body fluid. *Extracellular fluid*, the fluid outside the cells, includes interstitial fluid (the fluid between cells), lymph, and blood plasma (or hemolymph). In vertebrates, blood plasma, which is mainly water, transports nutrients, gases, waste products, and other materials throughout the body. **Interstitial fluid**, also called *tissue fluid*, forms from the blood plasma and bathes all the cells. Excess water evaporates from the body surface or is excreted by specialized structures.

Electrolytes are compounds such as inorganic salts, acids, and bases that form ions in solution. Electrolytes are very important solutes in body fluids. Many homeostatic mechanisms regulate fluid and electrolyte balance.

Recall from Chapter 5 that *osmosis* is the diffusion of water through a selectively permeable membrane. The net flow of water is from a more dilute solution (one with a lower solute concentration) to a less dilute solution (one with a higher solute concentration). If the solute concentrations of two solutions are equal, they are *isotonic* to each other. If solution A has a greater solute concentration than solution B, solution A is *hypertonic* to solution B. Solution B, with a lower solute concentration relative to solution A, is *hypotonic* to solution A. Remember that the total solute concentration of a solution is responsible for the direction of water movement. The *osmotic pressure* of a solution is the pressure that must be exerted on the hypertonic side of a selectively permeable membrane to prevent net movement of water from the hypotonic side.

An **osmole** is related to a mole (see Chapter 2), but takes into account the number of particles produced when a solute dissolves. For example, glucose dissolves to give only one kind of particle, so a mole of glucose in solution is one osmole. A mole of NaCl in solution produces two kinds of particles (Na^+ and Cl^-), so a mole of NaCl is two osmoles. Both types of ions affect the osmotic pressure of the solution. One *milliosmole* is 1/1000 of an osmole.

Osmolarity is a measure of the number of osmoles of solute per liter of solution. Solutions with the same osmolarity are described as *iso-osmotic*. If solution X has a higher osmolarity than solution Y, it is described as *hyperosmotic*. Solution Y would be described as *hypo-osmotic* relative to solution X.

Osmoregulation is the process by which animals regulate the concentration of water and salt in the body, allowing them to maintain their body fluids within homeostatic limits. **Excretion** is the process of discharging metabolic wastes from the body. **Excretory systems** have evolved that function in both osmoregulation and in disposal of metabolic wastes. Excretory systems rid the body of excess water and ions, metabolic wastes, and harmful substances. As we will discuss, hormones are important signaling molecules in these regulatory processes.

CHECKPOINT 48.1

- **CONNECT** How does osmoregulation contribute to homeostasis?
- What are the functions of excretory systems?

48.2 Metabolic Waste Products

LEARNING OBJECTIVE

- 2 Contrast the benefits and costs of excreting each of the following: ammonia, uric acid, or urea.

Metabolic wastes must be excreted so that they do not accumulate and reach concentrations that would disrupt homeostasis. The principal metabolic waste products produced by most animals are water, carbon dioxide, and *nitrogenous wastes*, those that contain nitrogen. Carbon dioxide is excreted mainly by respiratory structures (see Chapter 46). In terrestrial animals some water is also lost from respiratory surfaces. However, specialized excretory organs, such as kidneys, remove and excrete most of the water and nitrogenous wastes.

Nitrogenous wastes include ammonia, uric acid, and urea. Recall that amino acids and nucleic acids contain nitrogen. During the metabolism of amino acids, the nitrogen-containing amino group is removed (in a process known as *deamination*) and converted to *ammonia* (FIG. 48-1). However, ammonia is highly toxic. Some aquatic animals excrete ammonia into the surrounding water before it can build up to toxic concentrations in their tissues. A few terrestrial animals, including some snails and wood lice, vent it directly into the air. But many animals, humans included, convert ammonia to some less toxic nitrogenous waste such as uric acid or urea.

Uric acid is produced both from ammonia and by the breakdown of nucleotides from nucleic acids. Uric acid is insoluble in water and forms crystals that are excreted as a crystalline paste, so little fluid loss results. This excretion is an important water-conserving adaptation in many terrestrial animals, including insects, certain reptiles, and birds. Also, because uric acid is not toxic and can be safely stored, its excretion is an adaptive advantage for species whose young begin their development enclosed in eggs.

Urea, the principal nitrogenous waste product of amphibians and mammals, is synthesized in the liver from ammonia and carbon dioxide by a sequence of reactions known as the urea cycle. As in the production of uric acid, these reactions require specific enzymes and the input of energy by the cells. Compared with the energy cost of producing ammonia, the cost of producing urea and uric acid is high.

Urea has the advantage of being far less toxic than ammonia and can accumulate in higher concentrations without causing tissue damage; thus, it can be excreted in more concentrated form. Because urea is highly soluble, however, it is dissolved in water, and more water is needed to excrete urea than to excrete uric acid.

Figure 48-1 Formation of nitrogenous wastes

Deamination of amino acids and metabolism of nucleic acids produce nitrogenous wastes. Ammonia is the first metabolic product of deamination. Many aquatic animals excrete ammonia, but terrestrial animals convert it to urea and uric acid, which are less toxic than ammonia. Most amphibians and mammals convert ammonia to urea via the urea cycle. Insects and many reptiles, including birds, convert ammonia to uric acid. Energy is required to convert ammonia to urea and uric acid, but less water is required to excrete these wastes.

CHECKPOINT 48.2

- **CONNECT** Give examples of animals that excrete each of the principal types of nitrogenous wastes.
- What are the benefits of excreting nitrogenous wastes in the form of uric acid? in the form of urea?

48.3 Osmoregulation and Excretion in Invertebrates

LEARNING OBJECTIVES

- 3 Contrast osmoconformers and osmoregulators.
- 4 Compare the structure and function of protonephridia, metanephridia, and Malpighian tubules.

The ocean is a stable environment, and its salt concentration does not vary much. The electrolyte concentration in the cells and body fluids of marine sponges and cnidarians is very similar to sea water, so these animals do not require specialized excretory structures. They expend little or no energy in excreting wastes because wastes simply diffuse from their cells to the external environment and are washed away by water currents. When water stagnates and currents do not wash away wastes, aquatic environments, such as coral reefs, are damaged by the waste accumulation.

The body fluids of most marine invertebrates are in osmotic equilibrium with the surrounding sea water. These animals are known as **osmoconformers** because the concentration of their body fluids varies along with changes in the sea water. However, many osmoconforming marine animals still regulate some ions in their body fluids.

Coastal habitats, such as estuaries that contain brackish water, are much less stable environments than is the open ocean. Salt concentrations change frequently with shifting tides. Many invertebrates and vertebrates that inhabit coastal environments are **osmoregulators**. These animals have homeostatic mechanisms that maintain an optimal salt concentration in their tissues regardless of changes in the salt concentration of their surroundings.

In a coastal environment where fresh water enters the ocean, the water may have a lower salt concentration than the body fluids of an animal. Water osmotically moves into the animal's body, and salt diffuses out. An animal adapted to this environment has excretory structures that remove the excess water. Certain polychaete worms and the blue crab are among the animals that can be either osmoconformers or osmoregulators, depending on environmental conditions.

Dehydration is a constant threat to terrestrial animals. Because their fluid concentration is higher than that of the air around them, they tend to lose water by evaporation from both the body surface and respiratory surfaces. Terrestrial animals may also lose water as wastes are excreted. As animals moved onto the land, natural selection favored the evolution of structures and processes that conserve water.

Excretory systems help maintain fluid and electrolyte homeostasis by selectively adjusting the concentrations of salts and other substances in blood and other body fluids. Typically, an excretory system collects fluid, generally from the blood or interstitial fluid. It then adjusts the composition of this fluid by selectively returning needed substances to the body fluid. Finally, the body releases the adjusted excretory product containing excess or potentially toxic substances.

Nephridial organs are specialized for osmoregulation and/or excretion

Nephridial organs, or nephridia, are structures that function in osmoregulation and excretion in many invertebrates, including flatworms, nemerteans, rotifers, annelids, mollusks, and lancelets. Each nephridial organ consists of simple or branching tubes that typically open to the outside of the body through pores, called *nephridiopores*. Two types of nephridial organs are protonephridia and metanephridia.

Figure 48-2 Protonephridia of a flatworm

In flatworms and nemerteans, metabolic wastes pass through the body surface by diffusion, but these animals also have **protonephridia** (FIG. 48-2). The protonephridia are composed of tubules with no internal openings. Their enlarged blind ends consist of **flame cells** with brushes of cilia, so named because their constant motion reminded early biologists of flickering flames. The flame cells lie in the interstitial fluid that bathes the body cells. Fluid enters the flame cells, and the beating of the cilia propels the fluid through the tubules. Excess fluid leaves the body through nephridiopores.

Most annelids and mollusks have more complex nephridial organs called **metanephridia** (FIG. 48-3). Each segment of an earthworm has a pair of metanephridia. A metanephridium is a tubule open at both ends. The inner end opens into the coelom as a ciliated funnel, and the outer end opens to the outside through a nephridiopore. A network of capillaries surrounds each tubule. Fluid from the coelom passes into the tubule, bringing with it whatever it contains: glucose, salts, or wastes.

As fluid moves through the tubule, needed materials (e.g., water and glucose) are removed from the fluid by the tubule and are reabsorbed by the capillaries, leaving the wastes behind. In this way, urine that contains concentrated wastes is produced.

Malpighian tubules conserve water

The excretory system of insects and spiders consists of several hundred **Malpighian tubules** (FIG. 48-4). Malpighian tubules are slender extensions of the gut wall. Their blind ends lie in the hemocoel (blood cavity) and are bathed in hemolymph.

Cells of the tubule wall actively transport uric acid, potassium ions, and some other substances from the hemolymph into the tubule lumen. Other solutes and water follow by diffusion.

Figure 48-3 Metanephridium of an earthworm

Each metanephridium consists of a ciliated funnel opening into the coelom, a coiled tubule, and a nephridiopore opening to the outside. This 3-D internal view shows parts of three segments of the earthworm body.

Figure 48-4 Malpighian tubules of an insect

The slender Malpighian tubules have blind ends that extend into the hemocoel. Their cells transfer uric acid and some ions from the hemolymph into the tubule. Water follows by diffusion. The wastes are discharged into the gut. The epithelium that lines the rectum (part of the hindgut) actively reabsorbs most of the water and needed ions.

The Malpighian tubules empty into the gut. Water, some salts, and other solutes are reabsorbed into the hemolymph by a specialized epithelium in the rectum.

Uric acid, the major waste product, is excreted as a semidry paste with a minimum of water loss. Because Malpighian tubules effectively conserve body fluids, they have contributed to the success of insects in terrestrial environments.

CHECKPOINT 48.3

- **CONNECT** How are nephridial organs and Malpighian tubules alike? How are they different? (*Hint:* Consider both structure and function.)

48.4 Osmoregulation and Excretion in Vertebrates

LEARNING OBJECTIVES

- 5 Relate the function of the vertebrate kidney to the success of vertebrates in a wide variety of habitats.
- 6 Compare adaptations for osmoregulation in freshwater fishes, marine bony fishes, sharks, marine mammals, and terrestrial vertebrates.

Vertebrates live successfully in a wide range of habitats: in fresh water; in the ocean and tidal regions; and on land, even in extreme environments such as deserts. In response to the requirements of these diverse environments, adaptations have evolved for

regulating salt and water content and for excreting wastes. The main osmoregulatory and excretory organ in most vertebrates is the kidney. The **kidney** excretes most nitrogenous wastes and helps maintain fluid balance by adjusting the salt and water content of the urine. The skin, lungs or gills, and digestive system also help maintain fluid balance and dispose of metabolic wastes.

Freshwater vertebrates must rid themselves of excess water

As fishes began to move into freshwater habitats about 470 million years ago (mya), there must have been strong selection for adaptations that promoted effective osmoregulation. The evolution of body fluids more dilute than sea water was a major adaptation. However, the salt concentration of the body fluids of these fishes is still higher than that of the fresh water that surrounds them. They are hypertonic to their watery environment. As a result, water moves into the body, and they are in constant danger of becoming waterlogged.

Freshwater fishes are covered by scales and a mucous secretion that retard the passage of water into the body. However, water constantly enters through the gills and through the mouth (with food). How do these animals meet this challenge? The kidneys of freshwater fishes are adapted to excrete large amounts of very dilute urine (**FIG. 48-5a**). The kidneys have large *glomeruli*, capillary clusters that filter the blood in the first step in producing urine.

Water entry is only part of the challenge of osmoregulation in freshwater fishes. These animals also tend to lose salts by diffusion through the gills into the surrounding water. To compensate, special gill cells have evolved that actively transport salts (mainly sodium chloride) from the water into the body.

The gills of freshwater fishes excrete ammonia, their principal nitrogenous wastes. About 10% of nitrogenous wastes are excreted as urea.

Most amphibians are at least semi-aquatic, and their mechanisms of osmoregulation are similar to those of freshwater fishes. They, too, produce large amounts of dilute urine. In its urine and through its skin, a frog can lose an amount of water equivalent to one-third of its body weight in one day. Active transport of salt into the body by special cells in the skin compensates for loss of salt through skin and in urine. Adult amphibians generally inhabit moist environments. They excrete urea and reabsorb some water from the urinary bladder. When dehydrated, terrestrial frogs can dramatically decrease the process of urine production.

Marine vertebrates must replace lost fluid

Freshwater fishes adapted very successfully to their aquatic habitats. Thus, when some freshwater fishes returned to the sea about 200 mya, their blood and body fluids were less salty than their surroundings; that is, they were hypo-osmotic to their environment. These fishes lose water osmotically and take in salt through their gills and with their food. To compensate for fluid loss, many marine bony fishes drink sea water (**FIG. 48-5b**). They retain the water and excrete salt by the action of specialized cells in their gills.

Key Point

Adaptations for regulating water and salt concentration allow fishes to inhabit diverse environments, from freshwater lakes to salty oceans.

Figure 48-5 Osmoregulation in fishes

PREDICT A marine shark is spotted swimming in fresh water. How might this shark's kidney function be affected?

The gills are also responsible for ammonia excretion. Very little urine is excreted by the kidneys, which have only small (or no) glomeruli. The kidneys excrete certain excess ions (e.g., Mg^{2+}).

Marine cartilaginous fishes (sharks and rays) have different osmoregulatory adaptations that allow them to tolerate the salt concentrations of their environment. These animals accumulate and tolerate urea (**FIG. 48-5c**). Their tissues are adapted to function at concentrations of urea that would be toxic to most other animals. The high urea concentration makes the body fluids slightly hypertonic to sea water, resulting in a net inflow of water. Marine cartilaginous fishes have well-developed kidneys that excrete a large volume of urine. Excess salt is excreted by the kidneys and, in many species, by a rectal gland.

Certain non-avian reptiles and marine birds ingest sea water and take in a lot of salt in their food. Glands in their heads excrete salt. These salt glands are usually inactive; they function in response to osmotic stress. Non-avian reptiles and birds excrete uric acid, which conserves water.

Whales, dolphins, and other marine mammals ingest sea water along with their food. Their kidneys produce concentrated urine, much saltier than sea water. This physiological adaptation is important, especially for marine carnivores. The high-protein diet of these animals results in the production of large amounts of urea, which must be excreted in urine without losing much water.

Terrestrial vertebrates must conserve water

Amniotes (non-avian reptiles, birds, and mammals) have effective adaptations for life on land. Their skin minimizes water loss by evaporation, and many amniotes excrete uric acid, which requires very little water.

Because birds and mammals are endothermic (maintain a constant body temperature) and have a high rate of metabolism, they produce a relatively large volume of nitrogenous wastes. They have numerous adaptations, including very efficient kidneys, for conserving water. An extreme example is the desert-dwelling kangaroo rat, which obtains most of its water from its own metabolism. (Recall from Chapter 8 that aerobic respiration produces water. The kangaroo rat's kidneys are so efficient that it loses little fluid as urine.)

Birds conserve water by excreting nitrogen as uric acid and by efficiently reabsorbing water from the cloaca and intestine. Mammals excrete urea. Their kidneys produce very concentrated (hypertonic) urine.

In terrestrial vertebrates, the lungs, skin, and digestive system are important in osmoregulation and waste disposal (**FIG. 48-6**). Most carbon dioxide is excreted by the lungs. In birds and mammals, some water is lost from the body as water vapor in exhaled air. Although primarily concerned with the regulation of body temperature, the sweat glands of humans and some other mammals excrete 5% to 10% of all metabolic wastes.

(a) The kidney of terrestrial vertebrates conserves water by reabsorbing it. Birds and mammals can produce concentrated urine.

(b) Disposal of metabolic wastes in humans and other terrestrial mammals. Nitrogenous wastes are produced by the liver and transported to the kidneys. To conserve water, mammals produce a small amount of hypertonic urine. All cells produce carbon dioxide and some water during cellular respiration. These waste products are excreted by the lungs.

Figure 48-6 Excretory organs in terrestrial vertebrates

The liver produces both urea and uric acid, which are transported by the blood to the kidneys. Most of the bile pigments produced by the breakdown of red blood cells are excreted by the liver into the intestine. From the intestine they pass out of the body with the feces.

✓ CHECKPOINT 48.4

- **CONNECT** What type of osmoregulatory challenge is faced by marine fishes? by freshwater fishes? What mechanisms have evolved to meet these challenges?
- **CONNECT** What adaptations in aquatic birds and mammals help meet the challenges of osmoregulation and metabolic waste disposal? in terrestrial birds and mammals?

48.5 The Urinary System of Mammals

🎯 LEARNING OBJECTIVES

- 7 Describe (and label on a diagram) the organs of the mammalian urinary system and give the functions of each.
- 8 Describe (and label on a diagram) the structures of a nephron (including associated blood vessels) and give the functions of each structure.
- 9 Trace a drop of glomerular filtrate from Bowman's capsule to its release from the body as urine.
- 10 Describe regulation of fluid and electrolyte balance by antidiuretic hormone (ADH), the renin–angiotensin–aldosterone system, and atrial natriuretic peptide (ANP).

The mammalian **urinary system** consists of the kidneys, the urinary bladder, and associated ducts. The overall structure of the human urinary system is shown in **FIGURE 48-7**. Located just below the diaphragm in the “small of the back,” the kidneys look like a pair of giant, dark red lima beans, each about the size of a fist. Each kidney is covered by a connective tissue capsule (**FIG. 48-8**). The outer region of the kidney is the **renal cortex**, and the inner region is the **renal medulla**. The renal medulla contains eight to ten cone-shaped structures called **renal pyramids**. The tip of each pyramid is a **renal papilla**. Each papilla has several pores, the openings of **collecting ducts**.

As urine is produced, it flows from collecting ducts through a renal papilla and into the **renal pelvis**, a funnel-shaped chamber. Urine then flows into one of the paired **ureters**, ducts that connect each kidney with the **urinary bladder**. The urinary bladder is a remarkable organ capable of holding (with practice) up to 800 mL (about a pint and a half) of urine. Emptying the bladder changes it from the size of a small melon to that of a pecan. This feat is made possible by the smooth muscle and specialized epithelium of the bladder wall, which is capable of great shrinkage and stretching.

During **urination**, urine is released from the bladder and flows through the **urethra**, a duct leading to the outside of the body. In the male the urethra is lengthy and passes through the penis. Semen as well as urine passes through the male urethra. In the female the urethra is short and transports only urine. Its opening to the outside is just above the opening of the vagina. The length of the male urethra discourages bacterial invasions of the bladder. This length difference helps explain why bladder

Figure 48-7 The human urinary system

The kidneys produce urine, which passes through the ureters to the urinary bladder for temporary storage. During urination, the urethra conducts urine from the bladder to the outside of the body through an opening, the external urethral orifice.

Figure 48-8 Structure of the kidney

(a) **Location and the basic structure of a nephron.** Urine forms by filtration of the blood in the glomerulus and by adjustment of the glomerular filtrate as it passes through the series of tubules that drain Bowman's capsule.

(b) **Cutaway view of Bowman's capsule.** Note that the distal tubule is adjacent to the afferent and efferent arterioles. The juxtaglomerular apparatus (discussed later in the chapter) is a small group of cells located in the walls of the tubule and arterioles.

(c) **Low-power SEM of a portion of the kidney cortex.** The tissue was treated to remove some structures and to show glomeruli and associated blood vessels.

Figure 48-9 Nephron structure

infections are more common in females than in males. In summary, urine flows through the following structures:

kidney (through renal pelvis) → ureter → urinary bladder → urethra

The nephron is the functional unit of the kidney

The principal function of the kidneys is to help maintain homeostasis by regulating fluid balance and excreting metabolic wastes. However, the kidneys also have other functions. They produce the enzyme *renin*, which helps regulate fluid

balance and blood pressure (discussed later in the chapter), and at least two hormones: *erythropoietin*, which stimulates red blood cell production, and *1,25-dihydroxy-vitamin D₃*, which stimulates calcium absorption by the intestine.

Each kidney has up to one million functional units called **nephrons**. A nephron consists of a cuplike **Bowman's capsule** connected to a long, partially coiled **renal tubule** (FIG. 48-9). Positioned within Bowman's capsule is a cluster of capillaries called a **glomerulus**. Three main regions of the renal tubule are (1) the **proximal convoluted tubule** (or simply, *proximal tubule*), which conducts the *glomerular filtrate* (the fluid filtered from the blood) from Bowman's capsule; (2) the **loop of Henle**, an elongated, hairpin-shaped portion; and (3) the **distal convoluted tubule** (or *distal tubule*), which conducts the glomerular filtrate to a collecting duct. Thus, the glomerular filtrate passes through the following structures:

Bowman's capsule → proximal convoluted tubule → loop of Henle
→ distal convoluted tubule → collecting duct

The human kidney has two types of nephrons: the more numerous (85%) cortical nephrons and the more internal juxtamedullary nephrons (see Fig. 48-8b). *Cortical nephrons* have relatively small glomeruli and are located almost entirely within the cortex or outer medulla. *Juxtamedullary nephrons* have large glomeruli, and their very long loops of Henle extend deep into the medulla. The loop of Henle consists of a *descending limb* that receives glomerular filtrate from the proximal convoluted tubule and an *ascending limb*, through which the filtrate passes on its way to the distal convoluted tubule. The juxtamedullary nephrons contribute to the ability of the mammalian kidney to concentrate urine. Excretion of urine that is hypertonic to body fluids is an important mechanism for conserving water.

Key Point

The glomerulus filters blood. As the glomerular filtrate moves through the renal tubule, its composition is adjusted by selective reabsorption and tubular secretion. The adjusted filtrate is urine.

Figure 48-10 General regions of glomerular filtration, tubular reabsorption, and tubular secretion

PREDICT How would mild dehydration affect kidney function?

Blood is delivered to the kidney by the **renal artery**. Small branches of the renal artery give rise to **afferent arterioles** (*afferent* means “to carry toward”). An afferent arteriole conducts blood into the capillaries that make up each glomerulus. As blood flows through the glomerulus, some of the plasma is forced into Bowman’s capsule.

You may recall that in a typical circulatory route, capillaries deliver blood into veins. Circulation in the kidneys is an exception because blood flowing from the glomerular capillaries next passes into an **efferent arteriole**. Each efferent arteriole conducts blood *away* from a glomerulus. The efferent arteriole delivers blood to a second capillary network, the **peritubular capillaries** surrounding the renal tubule.

Blood is filtered as it flows through the first set of capillaries, those of the glomerulus. The peritubular capillaries receive blood containing materials reabsorbed from the renal tubule. Blood from the peritubular capillaries enters small veins that eventually lead to the **renal vein**. In summary, blood circulates through the kidney in the following sequence:

renal artery → an afferent arteriole → capillaries of a glomerulus → an efferent arteriole → peritubular capillaries → small veins → renal vein

Urine is produced by glomerular filtration, tubular reabsorption, and tubular secretion

Urine, the watery discharge of the urinary system, is produced by a combination of three processes: glomerular filtration, tubular reabsorption, and tubular secretion (**FIG. 48-10**).

Glomerular filtration is not selective with regard to ions and small molecules

Blood flows through the glomerular capillaries under high pressure, forcing more than 10% of the plasma out of the capillaries and into Bowman’s capsule. **Glomerular filtration** is similar to the mechanism whereby interstitial fluid is formed as blood flows through other capillary networks in the body. However, blood flow through glomerular capillaries is at much higher pressure, so more plasma is filtered in the kidney.

Several factors contribute to the production of a large amount of *glomerular filtrate*. First, the hydrostatic blood pressure in the glomerular capillaries is higher than in other capillaries. This high pressure is mainly due to the high resistance to outflow presented by the efferent arteriole, which is

smaller in diameter than the afferent arteriole. A second factor contributing to the large amount of glomerular filtrate is the large surface area for filtration provided by the highly coiled glomerular capillaries. A third factor is the great permeability of the glomerular capillaries. Numerous small pores between the endothelial cells that form their walls make the glomerular capillaries more porous than typical capillaries.

The wall of Bowman's capsule in contact with the capillaries consists of specialized epithelial cells called *podocytes*. These cells have numerous cytoplasmic extensions called *foot processes* that cover most of the surfaces of the glomerular capillaries (FIG. 48-11). Foot processes of adjacent podocytes are separated by narrow gaps called *filtration slits*. The porous walls of the glomerular capillaries and the filtration slits of the podocytes form a *filtration membrane* that permits fluid and small solutes dissolved in the plasma (including glucose, amino acids, sodium, potassium, chloride, bicarbonate, other salts, and urea) to pass through and become part of the glomerular filtrate. This filtration membrane holds back blood cells, platelets, and most of the plasma proteins.

The total volume of blood passing through the kidneys is about 1200 mL per minute, or about one-fourth of the entire cardiac output. As plasma passes through the glomerulus, it loses more than 10% of its volume to the glomerular filtrate.

The normal glomerular filtration rate amounts to about 180 L (about 45 gallons) each 24 hours, which is four and a half times the amount of fluid in the entire body! Common sense tells us that urine could not be excreted at that rate. Within a few moments, dehydration would become life-threatening.

Tubular reabsorption is highly selective The threat to homeostasis posed by the vast amounts of fluid filtered by the kidneys is avoided by **tubular reabsorption**. The renal tubules reabsorb about 99% of the glomerular filtrate into the blood, leaving only about 1.5 L to be excreted as urine during a 24-hour period. Tubular reabsorption permits precise regulation of blood chemistry by the kidneys. Wastes, excess salts, and other materials remain in the filtrate and are excreted in the urine, whereas needed substances such as glucose and amino acids are returned to the blood. Each day the tubules reabsorb more than 178 L of water, 1200 g (2.6 lb) of salt, and about 250 g (0.5 lb) of glucose. Most of it, of course, is reabsorbed many times over.

The simple epithelial cells lining the renal tubule are well adapted for reabsorbing materials. Their abundant microvilli increase the surface area for tubular reabsorption. These epithelial cells contain numerous mitochondria that provide the energy for running the cell pumps that actively transport materials.

Most (about 65%) of the glomerular filtrate is reabsorbed as it passes through the proximal convoluted tubule. Glucose, amino acids, vitamins, and other substances of nutritional value are entirely reabsorbed there. Many ions, including sodium, chloride, bicarbonate, and potassium, are partially reabsorbed. Some of these ions are actively transported; others are reabsorbed by diffusion. Tubular reabsorption continues as the glomerular filtrate passes through the loop of Henle and the distal convoluted tubule. Then the filtrate is further concentrated as it passes through the collecting duct that leads to the renal pelvis.

Substances that are useful to the body, such as glucose and amino acids, are normally reabsorbed from the renal tubules. If the concentration of a particular substance in the blood is high, however, the tubules may not be able to reabsorb it all. The maximum rate at which a substance can be reabsorbed is its **tubular transport maximum (T_m)**. When that rate is reached, the binding sites are saturated on the membrane proteins that transport the substance. For example, the tubular load of glucose is about 125 mg per minute, and almost all of it is normally reabsorbed. However, in a person with uncontrolled diabetes mellitus, the concentration of glucose in the blood exceeds its T_m

Figure 48-11 Filtration membrane of the kidney

The porous walls of the glomerular capillaries and the filtration slits between podocytes form a filtration membrane. This membrane is highly permeable to water, small molecules, and ions but restricts the passage of blood cells and large molecules.

(glucose concentration in excess of 320 mg per minute). The excess glucose cannot be reabsorbed and is excreted in the urine (glucosuria), a symptom of diabetes (discussed in Chapter 49).

Some substances are actively secreted from the blood into the glomerular filtrate

Tubular secretion is the selective transfer of substances from the blood in the peritubular capillaries into the renal tubule. Note that in tubular secretion ions and other substances are moved across the tubule epithelium in the opposite direction of tubular reabsorption. Potassium, hydrogen ions, and ammonium ions as well as some organic ions, such as creatinine (a metabolic waste), are secreted into the glomerular filtrate. Certain drugs, such as penicillin, are also removed from the blood by secretion. Secretion occurs mainly in the region of the distal convoluted tubule.

Secretion of hydrogen ions by the collecting ducts is an important homeostatic mechanism for regulating the pH of the blood. Carbon dioxide, which diffuses from the blood into the cells of the distal tubules and collecting ducts, combines with water, which produces carbonic acid. This acid then dissociates to form hydrogen ions and bicarbonate ions. When the blood becomes too acidic, the collecting ducts secrete more hydrogen ions into the urine:

Potassium ion secretion is another important homeostatic mechanism. When K^+ concentration is too high, nerve impulses are not effectively transmitted, and the strength of muscle contraction decreases. The heart rhythm becomes irregular, and cardiac arrest can occur. When K^+ concentration exceeds its homeostatic level, K^+ are secreted from the blood into the renal tubules and then excreted in the urine. Secretion results partly from a direct effect of the K^+ on the tubules. In addition, the adrenal cortex (a region of the adrenal gland) increases its output of the hormone *aldosterone*, which further stimulates secretion of K^+ .

Urine becomes concentrated as it passes through the renal tubule

We can survive with limited fluid intake because the kidneys can produce highly concentrated urine, more than four times as concentrated as blood. The osmolarity of human blood is about 300 milliosmoles per liter (mOsm/L). The kidneys can produce urine with an osmolarity of about 1200 mOsm/L.

As the glomerular filtrate passes through various regions of the renal tubule, salt (NaCl) is reabsorbed, establishing a salt concentration gradient in the interstitial fluid (FIGS. 48-12 and 48-13). The gradient is used to produce concentrated urine.

When glomerular filtrate flows from Bowman's capsule to the proximal tubule, its osmolarity is the same as that of blood (about 300 mOsm/L). Water and salt are reabsorbed from the proximal tubule. Sodium ions are actively transported out of the proximal tubule, and chloride follows passively. As salt passes into the interstitial fluid, water follows osmotically.

The walls of the descending limb of the loop of Henle are relatively permeable to water but relatively impermeable to

sodium and urea. The interstitial fluid has a high concentration of Na^+ , so as the glomerular filtrate passes down the loop of Henle, water moves out by osmosis. This process concentrates the filtrate inside the loop of Henle.

The loop of Henle is specialized to highly concentrate sodium chloride in the interstitial fluid of the medulla. It maintains a highly hypertonic interstitial fluid in the medulla near the bottom of the loop, which in turn lets the kidneys produce concentrated urine. At the turn of the loop of Henle, the walls become more permeable to salt and less permeable to water. As the concentrated glomerular filtrate begins to move up the ascending limb (the thin region), salt diffuses out into the interstitial fluid. This diffusion contributes to the high salt concentration of the interstitial fluid in the medulla surrounding the loop of Henle. Farther along the ascending limb (the thick region), sodium is actively transported out of the tubule.

Because water passes out of the descending limb of the loop of Henle, the glomerular filtrate at the bottom of the loop has a high salt concentration. However, because salt (but not water) is removed in the ascending limb, by the time the filtrate moves into the distal tubule, its osmolarity may be the same as or even lower than that of blood.

As it passes through the distal tubule, the filtrate may become even more dilute. The distal tubule is relatively impermeable to water but actively transports salt out into the interstitial fluid. The filtrate passes from the renal tubule into a larger collecting duct that eventually empties into the renal pelvis.

Note the *counterflow* of fluid through the two limbs of the loop of Henle. Glomerular filtrate passing down through the descending limb is flowing in a direction opposite that of the filtrate moving upward through the ascending limb. The filtrate becomes concentrated as it moves down the descending limb and diluted as it moves up the ascending limb. This countercurrent mechanism helps maintain a high salt concentration in the interstitial fluid of the medulla. The hypertonic interstitial fluid draws water osmotically from the filtrate in the collecting ducts.

The inner medullary collecting ducts are permeable to urea, so some of the concentrated urea in the filtrate can diffuse out into the interstitial fluid. The urea contributes to the high solute concentration of the inner medulla. This process helps concentrate urine.

The collecting ducts pass through the zone of very salty interstitial fluid. As the glomerular filtrate moves through the collecting duct, water passes osmotically into the interstitial fluid. Excess interstitial fluid continuously enters capillaries and becomes part of the blood. Sufficient water can leave the collecting ducts to produce a highly concentrated urine. Remember that a hypertonic urine conserves water.

Some of the water that diffuses from the filtrate into the interstitial fluid is removed by the *vasa recta*, which are long, straight capillaries that extend from the efferent arterioles of the juxta-medullary nephrons. The vasa recta extend deep into the medulla, only to negotiate a hairpin curve and return to the cortical venous drainage of the kidney. These capillaries parallel the renal tubules.

Blood flows in opposite directions in the ascending and descending regions of the vasa recta, just as glomerular filtrate flows in opposite directions in the ascending and descending

Figure 48-12 Movement of water, ions, and urea through the renal tubule and collecting duct

Water passes out of the descending limb of the loop of Henle, leaving a more concentrated filtrate inside. The heavy outline along the ascending limb indicates that this region is relatively impermeable to water. NaCl diffuses out from the lower (*thin*) part of the ascending limb. In the upper (*thick*) part of the ascending limb, NaCl is actively transported into the interstitial fluid. The saltier the interstitial fluid becomes, the more water moves out of the descending limb. This process leaves a concentrated filtrate inside, so more salt passes out. Note that this is a positive feedback system. Some urea also moves out into the interstitial fluid through the collecting ducts, contributing to its osmolarity. Water from the collecting ducts moves osmotically out into the hypertonic interstitial fluid and is carried away by capillaries. The concentrated solutes (NaCl and urea) are excreted in the urine.

limbs of the loop of Henle. As a consequence of this countercurrent flow, much of the salt and urea that enter the blood through the descending region of the vasa recta leave again from the ascending region. As a result, the solute concentration of the blood leaving the vasa recta is only slightly higher than that of the blood entering. This mechanism helps maintain the high solute concentration of the interstitial fluid in the renal medulla.

Urine consists of water, nitrogenous wastes, and salts

By the time the glomerular filtrate reaches the renal pelvis, its composition has been precisely adjusted. The adjusted filtrate, called *urine*, consists of approximately 96% water, 2.5% nitrogenous wastes (mainly urea), 1.5% salts, and traces of other substances, such as bile pigments, that may contribute to the characteristic color and odor. Healthy urine is sterile and has been used to wash battlefield wounds when clean water was not available. However, when exposed to bacterial action, urine swiftly decomposes and forms ammonia and other products. Ammonia produces the diaper rash of infants.

The composition of urine yields many clues to body function and malfunction. *Urinalysis*, the physical, chemical, and microscopic examination of urine, is a very important diagnostic tool that has been used to monitor diabetes mellitus and many other disorders. Urinalysis is also extensively used in drug testing because breakdown products of some drugs can be identified in the urine for several days or weeks after the drugs are ingested.

Hormones regulate kidney function

As we have discussed, the kidneys are vital in maintaining the body's fluid volume and electrolyte concentration. They help maintain the concentration of Na^+ and K^+ in the blood within narrow limits and also regulate blood pH. The endocrine system regulates these homeostatic functions of the kidneys.

Hormones involved include antidiuretic hormone (ADH), aldosterone, angiotensin II, and atrial natriuretic peptide (ANP) (TABLE 48-1).

ADH increases water reabsorption The amount of urine produced depends on the body's need to retain or rid itself of water. When fluid intake is low, the body begins to dehydrate, and the blood volume decreases. As blood volume decreases, the concentration of salts dissolved in the blood becomes greater, causing an increase in osmotic pressure. Certain receptors in the hypothalamus are sensitive to this osmotic change. They signal the posterior lobe of the pituitary gland to release **antidiuretic hormone (ADH)**. This hormone is actually produced in the hypothalamus, but it is stored in the posterior pituitary gland and is released as needed. A thirst center in the hypothalamus also responds to dehydration, stimulating an increase in fluid intake.

ADH makes the collecting ducts more permeable to water so that more water is reabsorbed. ADH temporarily increases the number of gated water channels in the plasma membranes of the collecting ducts. These channels allow water to pass rapidly through the plasma membrane. As a result, a small volume of concentrated urine is produced (FIG. 48-14).

When you drink a large volume of water, your blood becomes diluted, and its osmotic pressure falls. Release of ADH by the pituitary gland decreases, lessening the amount of water reabsorbed from the collecting ducts. The kidneys produce a large volume of dilute urine.

In the disorder *diabetes insipidus* (not to be confused with the more common disorder, diabetes mellitus), water is not efficiently reabsorbed from the ducts, so the body produces a large volume of urine. A person with severe diabetes insipidus may excrete up to 25 quarts of urine each day, a serious water loss. The affected individual becomes dehydrated and must drink almost continually to offset fluid loss. Diabetes insipidus results when the pituitary gland does not release enough

Figure 48-13 Concentration of the glomerular filtrate as it moves through the nephron

This figure shows the relative concentration of ions, mainly Na^+ and Cl^- , during production of a very concentrated urine. Numbers indicate the concentration of salt in the glomerular filtrate and interstitial fluid expressed in milliosmoles per liter. The more hypertonic a solution is, the higher its osmotic pressure. The very hypertonic interstitial fluid near the renal pelvis draws water osmotically from the filtrate in the collecting ducts. The heavy outline along the ascending loop indicates that this region is relatively impermeable to water.

ADH. This type of diabetes insipidus can be treated with a synthetic hormone (desmopressin). Diabetes insipidus can also develop from an acquired insensitivity of the kidney to ADH.

The renin-angiotensin-aldosterone pathway increases sodium reabsorption Sodium is the most abundant extracellular ion, accounting for about 90% of all positive ions in the extracellular fluid. Several hormones work together to regulate sodium concentration. **Aldosterone**, which is secreted by the cortex of the adrenal glands, stimulates the distal tubules and collecting ducts to increase sodium reabsorption. When researchers remove the adrenal glands of experimental animals, too much sodium is excreted, leading to serious depletion of the extracellular fluid.

Aldosterone secretion is stimulated both by hormones and by a decrease in blood pressure (caused by a decrease in volume of blood and interstitial fluid). When blood pressure falls, cells of the **juxtaglomerular apparatus** secrete the enzyme **renin**, which activates the **renin-angiotensin-aldosterone pathway**. The juxtaglomerular apparatus is a small group of cells in the region where the renal tubule contacts the afferent and efferent arterioles (see Fig. 48-9b). Renin converts the plasma protein angiotensinogen to **angiotensin I**. **Angiotensin-converting enzyme (ACE)** converts angiotensin I into its active form, **angiotensin II**, which is a peptide hormone. Angiotensin II stimulates aldosterone secretion. ACE is produced by the endothelial cells in the walls of pulmonary capillaries.

Table 48-1 Endocrine Regulation of Kidney Function

Hormone	Source	Target Tissue	Actions	Factors That Stimulate Release
Antidiuretic hormone (ADH)	Produced in hypothalamus; released by posterior pituitary gland	Collecting ducts	Increases permeability of collecting ducts to water, which increases tubular reabsorption and decreases water excretion	Low fluid intake decreases blood volume, which increases osmotic pressure of blood; receptors in hypothalamus stimulate posterior pituitary
Angiotensin II	Produced from angiotensin I	Blood vessels and adrenal glands	Constricts blood vessels, which raises blood pressure; stimulates aldosterone secretion; stimulates thirst	Decrease in blood pressure causes renin secretion; renin catalyzes conversion of angiotensinogen to angiotensin I, which is then converted to angiotensin II by ACE
Aldosterone	Adrenal glands (cortex)	Distal tubules and collecting ducts	Increases sodium reabsorption, which raises blood pressure	Angiotensin II; decrease in blood pressure
Atrial natriuretic peptide (ANP)	Atrium of heart	Afferent arterioles; collecting ducts	Dilates afferent arterioles; inhibits sodium reabsorption by collecting ducts; inhibits aldosterone secretion; decreases blood pressure	Stretching of atria due to increased blood volume

Key Point

When the body is dehydrated, the hormone ADH increases the permeability of the collecting ducts to water. More water is reabsorbed, which increases blood volume and decreases osmotic pressure.

Figure 48-14 Regulation of urine volume by antidiuretic hormone (ADH)

The hormone ADH helps maintain fluid homeostasis.

CONNECT What effect does ADH have on arterial blood pressure?

Angiotensin II increases the synthesis and release of aldosterone. Angiotensin II also raises blood pressure directly by constricting blood vessels. In addition, this hormone stimulates the posterior pituitary to release ADH and stimulates thirst. These actions help increase extracellular fluid volume, which raises blood pressure. In individuals with hypertension, *ACE inhibitors* are sometimes used to block the production

of angiotensin II. We can summarize the renin–angiotensin–aldosterone pathway as follows:

blood volume decreases → blood pressure decreases → cells of juxtaglomerular apparatus secrete renin → renin catalyzes conversion of angiotensinogen to angiotensin I → ACE catalyzes conversion of angiotensin I to angiotensin II → angiotensin II constricts blood vessels, which increases blood pressure, and stimulates aldosterone secretion → aldosterone increases sodium reabsorption → blood pressure increases

Atrial natriuretic peptide inhibits sodium reabsorption Atrial natriuretic peptide (ANP), a hormone produced by the heart, increases sodium excretion and decreases blood pressure. ANP is stored in granules in atrial muscle cells. When Na⁺ concentration increases, fluid is retained, and blood volume increases. As atrial muscle cells are stretched, they respond by releasing ANP into the circulation.

ANP dilates afferent arterioles, which increases the glomerular filtration rate. This hormone directly inhibits sodium reabsorption by the collecting ducts. ANP also acts indirectly by inhibiting aldosterone secretion. (Recall that aldosterone increases sodium reabsorption.) ANP reduces plasma aldosterone concentration by inhibiting renin release. These actions of ANP increase sodium excretion and urine output, which decreases blood volume and blood pressure. Note that the renin–angiotensin–aldosterone pathway works antagonistically with ANP in regulating fluid balance, electrolyte balance, and blood pressure.

blood volume increases → blood pressure increases → atria of heart stretched → atria release ANP → ANP directly inhibits sodium reabsorption and inhibits aldosterone secretion (which also inhibits sodium reabsorption) → urine volume increases → blood volume decreases → blood pressure decreases

CHECKPOINT 48.5

- **CONNECT** Which structure(s) is/are associated with each of the following functions: urea formation, urine formation, temporary storage of urine, and conduction of urine out of the body?
- **CONNECT** Which part(s) of the nephron is/are associated with each of the following processes: filtration, reabsorption, and secretion?
- **VISUALIZE** Draw a diagram showing the sequence of structures that a drop of glomerular filtrate passes through as it moves from Bowman's capsule to the urinary bladder.
- What are the main actions of the renin–angiotensin–aldosterone pathway? Compare the actions of this pathway with the actions of ANP.

Summary: Focus on Learning Objectives

48.1 Maintaining Fluid and Electrolyte Balance

(page 1033)

1 Describe how the processes of *osmoregulation* and *excretion* contribute to fluid and electrolyte homeostasis.

- **Osmoregulation** is the active regulation of osmotic pressure of body fluids so that fluid and electrolyte homeostasis is maintained. **Excretion** is the process of disposing of metabolic wastes.

48.2 Metabolic Waste Products (page 1033)

2 Contrast the benefits and costs of excreting each of the following: ammonia, uric acid, or urea.

- The principal waste products of animal metabolism are water; carbon dioxide; and *nitrogenous wastes*, including ammonia, uric acid, and urea. *Ammonia*, which is toxic, is excreted mainly by aquatic animals.
- **Uric acid** and **urea** are far less toxic than ammonia, but their synthesis requires energy. Uric acid can be excreted as a semisolid paste, a water-conserving adaptation. Urea excretion requires water.

48.3 Osmoregulation and Excretion in Invertebrates

(page 1034)

3 Contrast osmoconformers and osmoregulators.

- Most marine invertebrates are **osmoconformers**, meaning that the salt concentration of their body fluids varies with changes in the sea water. Some marine invertebrates, especially those inhabiting coastal habitats, are **osmoregulators** that maintain an optimal salt concentration despite changes in salinity of their surroundings.

4 Compare the structure and function of protonephridia, metanephridia, and Malpighian tubules.

- **Nephridial organs** help maintain homeostasis by regulating the concentration of body fluids through osmoregulation and excretion of metabolic wastes.
- **Protonephridia**, nephridial organs found in flatworms and nemerteans, are tubules with no internal openings. Interstitial fluid enters their blind ends, which consist of **flame cells**, cells with brushes of cilia. The cilia propel fluid through the tubules, and excess fluid exits through nephridiopores.
- Most annelids and mollusks have nephridial organs called **metanephridia**, which are tubules open at both ends. As fluid from the coelom moves through the tubule, needed materials are reabsorbed by capillaries. Urine, containing wastes, exits the body through nephridiopores.
- **Malpighian tubules**, extensions of the insect gut wall, have blind ends that lie in the hemocoel. Cells of the tubule actively transport uric acid and some other substances from the hemolymph into the tubule. Water follows by diffusion. The contents of the tubule pass into the gut. Water and some solutes are reabsorbed in the rectum.

Malpighian tubules have contributed to the success of insects as terrestrial animals.

48.4 Osmoregulation and Excretion in Vertebrates

(page 1036)

5 Relate the function of the vertebrate kidney to the success of vertebrates in a wide variety of habitats.

- The vertebrate **kidney** excretes nitrogenous wastes and helps maintain fluid balance by adjusting the salt and water content of the urine.
- Freshwater, marine, and terrestrial habitats present different problems for maintaining internal fluid balance and for the excretion of nitrogenous wastes. The structure and function of the vertebrate kidney have adapted to meet the various osmotic challenges presented by these different habitats.

6 Compare adaptations for osmoregulation in freshwater fishes, marine bony fishes, sharks, marine mammals, and terrestrial vertebrates.

- Freshwater fishes take in water osmotically, and they excrete a large volume of hypotonic urine.
- Marine bony fishes lose water osmotically. They compensate by drinking sea water and excreting salt through their gills; they produce only a small volume of isotonic urine. Sharks and other marine cartilaginous fishes retain large amounts of urea, allowing them to take in water osmotically through the gills. They excrete a large volume of hypotonic urine. Marine mammals ingest sea water with their food. They produce concentrated urine.
- Terrestrial vertebrates must conserve water. Endotherms have a high metabolic rate and produce a large volume of nitrogenous wastes. They have numerous adaptations for conserving water, including efficient kidneys.

48.5 The Urinary System of Mammals (page 1038)

7 Describe (and label on a diagram) the organs of the mammalian urinary system and give the functions of each.

- The **urinary system** is the principal excretory system in mammals. The kidneys produce urine, which passes through the **ureters** to the **urinary bladder** for storage. During urination, the urine is released from the body through the **urethra**.
- The outer portion of each kidney is the **renal cortex**, and the inner portion is the **renal medulla**. The renal medulla contains eight to ten *renal pyramids*. The tip of each pyramid is a *renal papilla*. As urine is produced, it flows into **collecting ducts**, which empty through a renal papilla into a funnel-shaped chamber, the **renal pelvis**. Each kidney has more than one million functional units called **nephrons**.

8 Describe (and label on a diagram) the structures of a nephron (including associated blood vessels) and give the functions of each structure.

- Each nephron consists of a cluster of capillaries called a **glomerulus**, which is surrounded by a **Bowman's capsule** that opens into a long, coiled **renal tubule**. The renal tubule consists of a **proximal convoluted tubule**, **loop of Henle**, and **distal convoluted tubule**.
- Cortical nephrons*, located almost entirely within the cortex, have small glomeruli. *Juxtamedullary nephrons* have large glomeruli and long loops of Henle that extend deep into the medulla. These nephrons are important in concentrating urine.
- Blood flows from small branches of the **renal artery** to **afferent arterioles** and then to glomerular capillaries. Blood then flows into an **efferent arteriole** that delivers blood into a second set of capillaries, the **peritubular capillaries** that surround the renal tubule. Blood leaves the kidney through the *renal vein*.

9 Trace a drop of glomerular filtrate from Bowman's capsule to its release from the body as urine.

- Urine is produced by **glomerular filtration** of plasma, **tubular reabsorption** of needed materials, and **tubular secretion** of a few substances, such as potassium and hydrogen ions, into the renal tubule.
- Plasma filters through the glomerular capillaries and into Bowman's capsule. The permeable walls of the capillaries and *filtration slits* between *podocytes*, specialized epithelial cells that make up the inner wall of Bowman's capsule, serve as a *filtration membrane*.
- Glomerular filtration is nonselective with regard to small molecules. In addition to metabolic wastes, glucose and other needed substances become part of the filtrate.
- Tubular reabsorption is a highly selective process that returns usable materials to the blood, but leaves wastes and excesses of other substances to be excreted in the

urine. The maximum rate at which a substance can be reabsorbed is its **tubular transport maximum (T_m)**.

- In tubular secretion, hydrogen ions, certain other ions, and some drugs are actively transported into the renal tubule to become part of the urine.
- Production of concentrated urine depends on a high salt and urea concentration in the interstitial fluid of the kidney medulla. The interstitial fluid in the medulla has a concentration gradient in which the salt is most concentrated around the bottom of the loop of Henle. This gradient is maintained, in part, by salt reabsorption from various parts of the renal tubule.
- A counterflow of fluid through the two limbs of the loop of Henle concentrates filtrate as it moves down the descending loop and dilutes it as it moves up the ascending loop.
- Water is drawn by osmosis from the filtrate as it passes through the collecting ducts. This process concentrates urine in the collecting ducts.
- Some of the water that diffuses from the filtrate into the interstitial fluid is removed by the *vasa recta*, a system of capillaries that extend from the efferent arterioles.
- Urine* is a watery solution of nitrogenous wastes, excess salts, and other unneeded substances.

10 Describe regulation of fluid and electrolyte balance by antidiuretic hormone (ADH), the renin–angiotensin–aldosterone system, and atrial natriuretic peptide (ANP).

- When the body needs to conserve water, the posterior pituitary gland increases its release of **antidiuretic hormone (ADH)**. The pituitary gland responds to an increase in osmotic concentration of the blood (caused by dehydration). ADH increases the permeability of the collecting ducts to water. As a result, more water is reabsorbed, and only a small volume of urine is produced.
- The renin–angiotensin–aldosterone pathway and atrial natriuretic peptide work antagonistically. When blood pressure decreases, cells of the **juxtaglomerular apparatus** secrete the enzyme **renin**, which activates a pathway leading to production of **angiotensin II**. This hormone stimulates aldosterone release. **Aldosterone** increases sodium reabsorption, and angiotensin II constricts arterioles; both actions raise blood pressure.
- When blood pressure increases, **atrial natriuretic peptide (ANP)** increases sodium excretion and inhibits aldosterone secretion. These actions increase urine output and lower blood pressure.

Test Your Understanding

Know and Comprehend

- The process that maintains homeostasis of body fluids by keeping them from becoming too dilute or too concentrated is (a) excretion (b) elimination (c) osmoregulation (d) glomerular filtration (e) tubular secretion
- Which of the following is *not* a correct pair? (a) proto-nephridia; flatworm (b) metanephridia; annelid (c) flame cell; flatworm (d) Malpighian tubule; mollusk (e) kidney; vertebrate
- To compensate for fluid loss, many marine bony fishes (a) accumulate urea (b) have glands that excrete glucose (c) eat a low-protein diet (d) excrete a large volume of hypertonic urine (e) drink sea water
- The afferent arteriole delivers blood to the (a) renal artery (b) efferent arteriole (c) renal vein (d) capillaries of the glomerulus (e) peritubular capillaries
- Which of the following does *not* contribute to the process of filtration? (a) active transport by epithelial cells lining renal

tubules (b) large surface area for filtration (c) low permeability of glomerular capillaries (d) high hydrostatic blood pressure in glomerular capillaries (e) podocytes

6. Tubular transport maximum (T_m) is (a) the maximum rate at which a substance in the filtrate can be reabsorbed into the blood from the renal tubules (b) the most rapid rate at which urine can be transported through the ureter (c) the maximum rate at which a substance can be reabsorbed by the glomerulus (d) the maximum rate at which a substance can pass through the loop of Henle (e) the maximum amount of a substance that can be secreted into the filtrate
7. Which of the following does *not* contribute to the high salt concentration in the interstitial fluid of the kidney medulla? (a) active transport of sodium from the upper part of the ascending limb (b) diffusion of salt from the ascending limb of the loop of Henle (c) reabsorption of salt from various regions of Bowman's capsule (d) counterflow of fluid through the two limbs of the loop of Henle (e) diffusion of urea out of the collecting duct
8. Which is *not* true of ADH? (a) released by posterior lobe of the pituitary gland (b) increases water reabsorption (c) secretion increases when osmotic pressure in body increases (d) increases urine volume (e) secretion decreases when you drink a lot of water
9. Aldosterone (a) is released by the posterior pituitary gland (b) decreases sodium reabsorption (c) secretion is stimulated by an increase in blood pressure (d) is an enzyme that converts angiotensin into angiotensin II (e) secretion increases in response to angiotensin II

Apply and Analyze

10. Arrange the following structures into an accurate sequence through which urine passes. 1. urethra 2. urinary bladder 3. kidney 4. ureter (a) 4, 3, 2, 1 (b) 3, 4, 2, 1 (c) 1, 2, 3, 4 (d) 4, 2, 1, 3 (e) 3, 1, 2, 4
11. Arrange the following structures into an accurate sequence through which glomerular filtrate passes. 1. proximal convoluted tubule 2. loop of Henle 3. collecting duct 4. distal convoluted tubule 5. Bowman's capsule (a) 5, 4, 3, 2, 1 (b) 3, 4, 2, 5, 1 (c) 1, 5, 2, 3, 4 (d) 5, 4, 2, 3, 1 (e) 5, 1, 2, 4, 3
12. **VISUALIZE** Label the diagram.

13. **CONNECT** Glucose is normally present in the glomerular filtrate, but not in the urine. Persons with uncontrolled diabetes mellitus are an exception. They have glucose in their urine, as well as increased urine output. Develop a hypothesis to explain these exceptions.
14. What types of osmoregulatory challenges do humans experience? Explain. What mechanisms do we have to meet these challenges?

Evaluate and Synthesize

15. **EVOLUTION LINK** The number of protonephridia in a planarian is related to the salinity of its environment. Planaria inhabiting slightly salty water develop fewer protonephridia than those inhabiting less salty water, but the number of protonephridia quickly increases when the concentration of salt in the environment is lower. How is this increase adaptive? Explain.
16. **EVOLUTION LINK** The kangaroo rat's diet consists of dry seeds, and it drinks no water. What types of osmoregulatory adaptations might help this animal survive?
17. **EVOLUTION LINK** Although the kidney is basically similar in all vertebrates, its structure and function vary somewhat among vertebrate taxa. What are some of the adaptations that have occurred during the evolution of the vertebrate kidney?
18. **SCIENCE, TECHNOLOGY, AND SOCIETY** A person with kidney disease lives 10 to 15 years longer with a kidney transplant than on continued dialysis. However, in the United States many individuals have difficulty being accepted by a transplant program because they do not have adequate insurance or other resources. The immunosuppressive drugs and other medications required after the surgery are also very expensive, costing about \$2500 per month. Should economic status be a deciding factor about whether a person lives or dies? or about quality of life?

49 Endocrine Regulation

KEY CONCEPTS

- 49.1** Endocrine glands and tissues secrete hormones, chemical messengers that bind to specific receptors on (or in) target cells and regulate physiological processes. Endocrine regulation depends mainly on negative feedback systems.
- 49.2** Several types of endocrine signaling are known: in classical endocrine signaling, endocrine glands secrete hormones that are transported to target cells by the blood; in neuroendocrine signaling, neuroendocrine cells produce hormones that are transported down axons and released into interstitial fluid; in autocrine signaling, a hormone acts on the very cells that produce it; and in paracrine signaling, a hormone acts on nearby cells.
- 49.3** Receptors are responsible for the specificity of the endocrine system. Small, lipid-soluble hormones enter target cells, bind to receptors inside the cell, and then activate or repress specific genes; hydrophilic hormones bind to cell-surface receptors and initiate signal transduction, leading to changes in cell processes.
- 49.4** Many invertebrate hormones are neurohormones secreted by neuroendocrine cells. Invertebrate hormones regulate metabolism, growth, and development, including molting and metamorphosis.
- 49.5** In vertebrates, many organs and tissues secrete hormones that interact to regulate growth and development, metabolism, fluid balance, response to stress, reproduction, and many other processes.

A caterpillar becomes a butterfly. A crustacean changes color to blend with its background (see photograph). A young girl develops into a woman. An adult copes with chronic stress. The **endocrine system** regulates these physiological processes and many more, including growth and development; metabolism; fluid balance and concentrations of specific ions and chemical compounds in the blood, urine, and other body fluids; reproduction; and response to stress. The tissues and organs of the endocrine system secrete *hormones*, chemical messengers that signal other cells.

Endocrinology, the study of endocrine activity, is an active, exciting field of biomedical research. This branch of biology has its roots in experiments performed by German physiologist A.A. Berthold in the 1840s. Berthold removed the testes from young roosters and observed that the roosters' combs (a male secondary sex characteristic) did not grow as large as those in normal roosters. He then transplanted testes into some of the birds and observed that the combs grew to normal size. Berthold's methods became a model for subsequent studies in endocrinology and are still used by researchers today.

Investigators are actively studying mechanisms of hormone action, including characterizing receptors and identifying the molecules involved in *signal transduction*. Some endocrinologists use a reverse strategy for discovering new hormones and signaling pathways within the cell. They focus on "orphan" nuclear receptors, those for which ligands (the molecules that bind with them) are not yet known. Some of these "orphan" receptors are receptors for hormones that have not yet been identified. Using this strategy,

PHOTO: Endocrine regulation of color changes in a crustacean. Hormones regulate the distribution of pigment in the cells, resulting in color changes. This Puget Sound king crab (*Lopholithodes mandtii*) blends with its background by changing color. WaterFrame/Alamy Stock Photo

researchers have identified intracellular signaling pathways for steroids, fatty acids, and several other compounds. Interestingly, many signaling pathways share the same molecules even though they respond to different stimuli and activate different responses. Much remains to be learned about how similar pathways lead to many different, and very specific, cell actions.

In this chapter we discuss how the endocrine system regulates life processes. We focus on how hormones maintain homeostasis, and we examine how overproduction or deficiency of various hormones interferes with normal functioning.

49.1 An Overview of Endocrine Regulation

LEARNING OBJECTIVES

- 1 Compare endocrine system function with nervous system function and describe how these systems work together to regulate body processes.
- 2 Summarize the regulation of endocrine action by negative feedback systems.
- 3 Identify four main chemical groups to which hormones are assigned and give two examples for each group.

The endocrine system is a diverse collection of cells, tissues, and organs including specialized **endocrine glands** that produce and secrete **hormones**, chemical messengers that regulate many physiological processes. The term *hormone* is derived from a Greek word meaning “to excite.” Hormones excite, or stimulate, changes in specific tissues. Endocrine glands differ from **exocrine glands** (such as sweat glands and gastric glands) that release their secretions into ducts. Endocrine glands have no ducts and secrete their hormones into the surrounding interstitial fluid or blood.

Endocrinologists have identified about ten discrete endocrine glands. They have also discovered specialized cells in the digestive tract, heart, kidneys, and many other parts of the body that release hormones or hormone-like substances. As a result of these discoveries, the scope of endocrinology now includes the production and actions of chemical messengers produced by a wide variety of organs, tissues, and cells.¹

Hormones are typically transported by the blood. They produce a characteristic response only after they bind with specific receptors on **target cells**, the cells influenced by a particular hormone. Target cells may be in another endocrine gland or in an entirely different type of organ, such as a bone or kidney. Target cells may be located far from the endocrine gland. For example, the vertebrate thyroid gland secretes hormones that stimulate metabolism in tissues throughout the body.

¹ Pheromones are chemical messengers that animals release to communicate with other animals of the same species. Most biologists do not classify pheromones as hormones because pheromones are generally produced by exocrine glands and do not regulate metabolic activities within the animal that produces them. Their role in regulating behavior is discussed in Chapter 52.

Several types of hormones may be involved in regulating the metabolic activities of a particular type of cell. In fact, many hormones produce a synergistic effect in which the presence of one hormone enhances the effects of another.

The endocrine system and nervous system interact to regulate the body

The endocrine system works closely with the nervous system to maintain **homeostasis**, the balanced internal environment of the body. Recall from Chapters 41 and 42 that the nervous system responds rapidly to stimuli by transmitting electrical and chemical signals. Neurons signal muscle and gland cells, including endocrine cells. The endocrine system signals a much wider range of target cell types than the nervous system does.

In general, the endocrine system responds more slowly than the nervous system, but its responses may be longer-lasting. As we will learn, the nervous system helps regulate many endocrine responses. For example, when the body is threatened, the hypothalamus signals the adrenal glands to secrete the hormone epinephrine. The hypothalamus, which is the link between the nervous and endocrine systems, also produces several hormones (neurohormones), including hormones that regulate the pituitary gland.

Nervous system and endocrine function further blur when we consider that the same signal molecule can function as either a neurotransmitter or a hormone, depending on its source. (You may recall from Chapters 41 and 42 that norepinephrine is secreted at synapses by neurons in the brain and by the sympathetic system.) Norepinephrine is also secreted as a hormone by the adrenal medulla, an endocrine organ.

Negative feedback systems regulate endocrine activity

Although present in minute amounts, more than 50 different hormones may be circulating in the blood of a vertebrate at any given time. Hormone molecules continuously move out of the circulation and bind with target cells. They are also removed from the blood by the liver, which inactivates some hormones, and by the kidneys, which excrete them.

Most endocrine action is regulated by **negative feedback systems**, discussed in Chapter 39. The parathyroid glands, located in the neck of tetrapod vertebrates, provide a good example of how negative feedback works in endocrine regulation (**FIG. 49-1**). The parathyroid glands regulate the calcium concentration of the blood. When the calcium concentration is not within homeostatic limits, nerves and muscles cannot function properly. For instance, when too few calcium ions are present, neurons fire spontaneously, causing muscle spasms. When calcium concentration varies too far from the steady state (either too high or too low), negative feedback systems restore homeostasis.

A decrease in calcium concentration in the plasma signals the parathyroid glands to release more parathyroid hormone. This hormone increases the concentration of calcium in the blood. When the calcium concentration rises above normal

Figure 49-1 Regulation by negative feedback

Whether the calcium concentration in the blood is too high or too low, negative feedback mechanisms restore homeostasis. Parathyroid hormone increases calcium concentration by stimulating calcium release from bones and calcium reabsorption from the kidney tubules. The green area represents the homeostatic range. (See Figure 49-11 for more detailed diagrams of parathyroid hormone regulation.)

limits, the parathyroid glands slow their output of hormone. Both responses are negative feedback systems. An increase in calcium concentration results in decreased release of parathyroid hormone, whereas a decrease in calcium leads to increased hormone secretion. In each case, the response counteracts the inappropriate change, restoring the steady state. (Parathyroid action is discussed in greater detail later in the chapter.)

Hormones are assigned to four chemical groups

Although hormones are chemically diverse, they generally belong to one of four chemical groups: (1) fatty acid derivatives, (2) steroids, (3) amino acid derivatives, or (4) peptides or proteins. *Prostaglandins* and the juvenile hormones of insects are **fatty acid derivatives** (FIG. 49-2a). Prostaglandins are synthesized from arachidonic acid, a 20-carbon fatty acid. A prostaglandin has a 5-carbon ring in its structure.

The molting hormone of insects is a **steroid hormone** (FIG. 49-2b). In vertebrates, the adrenal cortex, testis, ovary, and placenta secrete steroid hormones synthesized from cholesterol. Examples of steroid hormones are cortisol, secreted by the adrenal cortex; the male reproductive hormone testosterone secreted by the testis; and the female reproductive hormones progesterone and estrogen produced by the ovary. Athletes (and others) sometimes abuse synthetic hormones known as anabolic steroids (see *Inquiring About: Anabolic Steroids and Other Performance-Enhancing Drugs*).

Chemically, the simplest hormones are **amino acid derivatives** (FIG. 49-2c). The thyroid hormones (T_3 and T_4) are synthesized from the amino acid tyrosine and iodide. Epinephrine (also known as adrenaline) and norepinephrine

(also known as noradrenaline), produced by the medulla of the adrenal gland, are also derived from tyrosine. Melatonin is synthesized from the amino acid tryptophan.

The water-soluble **peptide hormones** are the largest hormone group. (Many endocrinologists include protein hormones in this group.) **Neuropeptides** are a large group of signaling molecules produced by neurons. Oxytocin and antidiuretic hormone (ADH), produced in the hypothalamus, are short neuropeptides, each composed of nine amino acids (FIG. 49-2d). Seven of the amino acids are identical in the two hormones, but the actions of these hormones are quite different. The hormones glucagon (see Fig. 3-19), secretin, adrenocorticotrophic hormone (ACTH), and calcitonin are somewhat longer peptides that each consist of about 30 amino acids.

Insulin is a small protein that consists of two peptide chains joined by disulfide bonds. Growth hormone, thyroid-stimulating hormone, and the gonadotropic hormones, all secreted by the anterior pituitary gland, are large proteins with molecular weights of 25,000 or more.

CHECKPOINT 49.1

- What are target cells?
- **CONNECT** How do the nervous and endocrine systems work together?
- **PREDICT** The concentration of calcium in the blood decreases below the homeostatic level. How does the body respond?
- What are four major chemical groups of hormones? Give an example of each.

(a) Hormones derived from fatty acids.

(b) Steroid hormones.

(c) Amino acid derivatives.

(d) Peptide hormones.

Figure 49-2 Major chemical groups of hormones

49.2 Types of Endocrine Signaling

LEARNING OBJECTIVE

4 Compare four types of endocrine signaling.

Hormones signal their target cells by classical endocrine signaling, neuroendocrine signaling, autocrine signaling, and paracrine signaling. In *classical endocrine signaling*, hormones are secreted by endocrine glands and are transported by the blood to target cells (FIG. 49-3a). Steroid hormones and thyroid hormones are transported bound to plasma proteins. The water-soluble peptide hormones are dissolved in the plasma. Hormones move out of the blood with plasma and are present in interstitial fluid.

Neurohormones are transported in the blood

Certain neurons, known as **neuroendocrine cells**, are an important link between the nervous and endocrine systems. In *neuroendocrine signaling*, neuroendocrine cells produce **neurohormones** that are transported down axons and released into the interstitial fluid. They typically diffuse into capillaries and are transported by the blood (FIG. 49-3b). Invertebrate endocrine systems are largely neuroendocrine. In vertebrates, the hypothalamus produces neurohormones that link the nervous system with the pituitary gland, an endocrine gland that secretes several hormones.

Some local regulators are considered hormones

A **local regulator** is a signaling molecule that diffuses through the interstitial fluid and acts on nearby cells. Most endocrinologists include at least certain local regulators as hormones. Also, some chemical compounds that act as classical hormones (transported by the blood) function as local regulators under some conditions.

Local regulators use *autocrine* or *paracrine* signaling. In *autocrine signaling*, a hormone or other regulator acts on the very cells that produce it (FIG. 49-3c). For example, the female hormone estrogen, which

Anabolic Steroids and Other Performance-Enhancing Drugs

Why are anabolic steroids and some other performance-enhancing drugs abused? An estimated one million people in the United States, half of them adolescents, abuse certain hormones so as to enhance their physical performance. Anabolic steroids, a group of synthetic hormones, are officially called anabolic-androgenic steroids. Anabolic steroids are synthetic androgens (male reproductive hormones) that were developed in the 1930s to prevent muscle atrophy in patients with diseases that prevented them from moving.

In the 1950s, anabolic steroids became popular with professional athletes, who used them to increase muscle mass, physical strength, endurance, and aggressiveness. In truth, their athletic performance was probably enhanced, at least in part, by drug-induced euphoria and increased enthusiasm for training. The term *doping* refers to the use of banned performance-enhancing drugs.

As with other hormones, the concentration of steroids circulating in the body is precisely regulated, so use of anabolic steroids interferes with normal physiological processes. These drugs remain in the body for a long time. Their metabolites (breakdown products) can be detected in the urine for up to six months.

Even during short-term use and at relatively low doses, anabolic steroids have a significant effect on mood and behavior. At higher doses users experience disturbed thought processes, forgetfulness, and confusion and often find themselves easily distracted. The term *roid rage* refers to the mood swings, unpredictable anger,

increased aggressiveness, and irrational behavior exhibited by many users.

Misuse of anabolic steroids poses many health hazards. These drugs increase the risk of cardiovascular disease by elevating blood pressure and decreasing the concentration of high-density lipoproteins (HDL, or “good” cholesterol). Anabolic steroids cause kidney and liver damage as well as increase the risk of liver cancer. Abuse of these hormones also reduces sexual function. In males, testosterone secretion decreases and the testes shrink, leading to sterility. In females, abuse of anabolic steroids can cause infertility as well as masculine features such as facial hair and decreased breast size. In adolescents, these steroids cause severe acne and stunt growth by prematurely closing the growth plates in bones.

Anabolic steroids are both injected and taken in pill form. Steroid abusers who share needles or use nonsterile techniques when they inject steroids are at risk for contracting hepatitis, HIV, and other serious infections.

When their serious side effects became known in the 1960s, anabolic steroid use became controversial, and in 1973 the Olympic Committee banned their use. They are now prohibited worldwide by amateur and professional sports organizations. In the United States, possession of anabolic steroids without a prescription is a federal offense. However, despite the risks, the black market for these synthetic hormones is estimated at more than \$1 billion per year.

A recent analysis determined that almost one-third of anabolic steroids purchased illegally did not contain the drugs listed on their

labels. Almost 50% of anabolic steroids that did contain the promised drug were delivered in much lower or much higher dosage. In addition, illegally purchased drugs are often contaminated with toxic heavy metals (e.g., lead and arsenic).

The typical anabolic steroid user is a male (95%) athlete (65%), most often a football player, weight lifter, or wrestler. Surprisingly, though, about 10% of male high school students have used anabolic steroids, and about one-third of these students are not even on a high school team. These adolescents use the hormone only to change their physical appearance—to pump up their muscles (“bulk up”)—and increase endurance. Many anabolic steroid users have difficulty realistically perceiving their body images. They remain unhappy even after dramatic increases in muscle mass.

Some people also abuse other hormones, including human growth hormone (HGH) and erythropoietin, to enhance performance. HGH, like anabolic steroids, helps build muscle mass but also causes acromegaly, a condition in which certain bones thicken abnormally. HGH can also cause diabetes and increase heart size, which can lead to heart failure.

Erythropoietin, a hormone produced by the kidney, increases the concentration of red blood cells, which increases oxygen transport. This hormone can enhance the performance of an endurance athlete by as much as 10% for short periods. However, abnormally high concentrations of red blood cells can cause serious cardiovascular problems. Erythropoietin abuse has caused the deaths of several athletes.

functions as a classical hormone, can also exert an autocrine effect that stimulates additional estrogen secretion. At times, estrogen acts on nearby cells, a type of local regulation known as *paracrine signaling* (FIG. 49-3d).

Local regulators include chemical mediators such as growth factors, histamine, nitric oxide, and prostaglandins. More than 50 **growth factors**, typically peptides, stimulate cell division and normal development in specific types of cells. Recall from Chapter 45 that **histamine** is stored in mast cells and is released in response to allergic reactions, injury, or infection. Histamine causes blood vessels to dilate and capillaries to become more permeable. **Nitric oxide (NO)**, another local regulator, is a gas produced by many types of cells, including those lining blood vessels. NO relaxes smooth muscle fibers in the blood vessel wall, causing the blood vessel to dilate. (See discussion of nitric oxide in Chapter 6.)

Prostaglandins are modified fatty acids released continuously by the cells of most tissues. These local hormones use paracrine signaling. Although present in very small quantities,

prostaglandins affect a wide range of physiological processes. They modify cyclic AMP levels and interact with other hormones to regulate various metabolic activities.

The major prostaglandin target is smooth muscle. Some prostaglandins stimulate smooth muscle to contract, whereas others cause relaxation. Thus, some reduce blood pressure, whereas others raise it. Prostaglandins synthesized in the temperature-regulating center of the hypothalamus cause fever. In fact, nonsteroidal anti-inflammatory drugs (NSAIDs), such as aspirin and ibuprofen, reduce fever and decrease inflammation and pain by inhibiting prostaglandin synthesis.

Because prostaglandins are involved in the regulation of so many metabolic processes, they have great potential for a variety of clinical uses. Physicians use them to induce labor in pregnant women, to induce abortion, and to promote the healing of ulcers in the stomach and duodenum. Prostaglandins may someday be used to treat a variety of illnesses, including asthma, arthritis, kidney disease, certain cardiovascular disorders, and some forms of cancer.

Figure 49-3 Some types of endocrine signaling

Endocrine cells secrete hormones that signal target cells, leading to a change in one or more cell processes.

CHECKPOINT 49.2

- **VISUALIZE** Draw diagrams to contrast neuroendocrine signaling with classical endocrine signaling.
- How are autocrine and paracrine signaling different?
- What are two functions of prostaglandins?

49.3 Mechanisms of Hormone Action

LEARNING OBJECTIVE

- 5 Compare the mechanism of action of small, lipid-soluble hormones with that of hydrophilic hormones; include the role of second messengers, such as cyclic AMP.

A hormone present in the interstitial fluid remains “unnoticed” until it comes in contact with its target cells and binds to specific receptors on the cell surface or inside the cell. Recall that the receptor site is somewhat similar to a lock, and the hormones are like different keys. Only the hormone that fits the specific receptor can influence the metabolic machinery of the cell (see Chapter 6). Receptors are responsible for the specificity of the endocrine system.

Receptors are continuously synthesized and degraded. Their numbers are decreased or increased by **receptor down-regulation** and **receptor up-regulation**. For example, when the concentration of a hormone is too high for an extended period, cells decrease the number of receptors for that hormone. Down-regulation decreases the sensitivity of target cells to the hormone, so it dampens the hormone’s ability to carry out its function. Up-regulation occurs when the concentration of a particular hormone is too low. Increasing the number of receptors on the plasma membrane increases the hormone’s effect on the cell.

Lipid-soluble hormones enter target cells and activate genes

Steroid hormones and thyroid hormones are relatively small, lipid-soluble (hydrophobic) molecules that easily pass through the plasma membrane of the target cell. Specific protein receptors in the cytoplasm or in the nucleus bind with the hormone to form a hormone–receptor complex (FIG. 49-4). For example, thyroid hormones bind with receptors in the nucleus that are transcription factors. When activated by the hormone, they activate or repress transcription of messenger RNA coding for specific proteins. Proteins that are synthesized produce changes in structure or metabolic activity.

Gene activation and protein synthesis may take several hours. However, steroid hormones may also have more

Key Point

Steroid and thyroid hormones are small, lipid-soluble molecules that pass through the plasma membrane; they pass into the nucleus where they activate or repress specific genes. Specific proteins are synthesized, leading to the changes we recognize as the hormone's actions.

Figure 49-4 Mechanism of action of steroid and thyroid hormones

PREDICT What would happen if the number of receptors in the nucleus were severely decreased?

rapid mechanisms of action that do not require protein synthesis. For example, when an estrogen receptor in the membrane of the endoplasmic reticulum is activated by estrogen binding, it initiates rapid signaling that leads to changes in the cell within minutes or even seconds. Plasma

membrane receptors have been described for at least two steroid hormones.

Water-soluble hormones bind to cell-surface receptors

Because peptide hormones are hydrophilic, they are not soluble in the lipid layer of the plasma membrane and do not enter the target cell. Instead, they bind to specific cell-surface receptors in the plasma membrane. Two main types of cell-surface receptors that bind hormones are G protein-linked receptors and enzyme-linked receptors. These receptors were discussed in Chapter 6. Here we will review some basic concepts.

G protein-linked receptors initiate signal transduction

G protein-linked receptors are transmembrane proteins that initiate **signal transduction**; they convert an extracellular hormone signal into an intracellular signal that affects some cell process. The hormone does not enter the cell. It serves as the **first messenger** and relays information to a **second messenger**, or intracellular signal. The second messenger then signals effector molecules that carry out the action.

G protein-linked receptors activate **G proteins**, a group of integral regulatory proteins (FIG. 49-5). The G indicates that they bind *guanosine triphosphate (GTP)*, which, like ATP, is an important molecule in energy reactions. When the system is inactive, G protein binds to *guanosine diphosphate (GDP)*, which is similar to ADP, the hydrolyzed form of ATP. G proteins shuttle a signal between the receptor and a second messenger.

When a hormone-bound receptor binds to it, a stimulatory G protein releases GDP and replaces it with GTP. The G protein undergoes a change in shape that allows it to

bind with and activate the enzyme **adenylyl cyclase** on the cytoplasmic side of the plasma membrane. Once activated, adenylyl cyclase catalyzes the conversion of ATP to **cyclic AMP (cAMP)**. By coupling the hormone-receptor complex to an enzyme that generates a signal, G proteins amplify

Peptide hormones bind with receptors on the plasma membrane. The receptor is a signal transducer that converts the hormone signal to an intracellular signal.

Figure 49-5 Mechanism of action of peptide hormones

Many peptide hormones signal target cells by way of a G protein-linked receptor. Cyclic AMP, or some other second messenger, relays the signal by activating a cascade of phosphorylation reactions. The final protein in the pathway changes some cell process.

PREDICT What would happen if adenylyl cyclase were inhibited?

hormone effects, and many second-messenger molecules are rapidly produced. One type of G protein, G_s , stimulates adenylyl cyclase, and another, G_i , inhibits it.

Cyclic AMP activates **protein kinases**, enzymes that phosphorylate (add a phosphate group to) specific proteins. When phosphorylated, protein kinase is activated and may phosphorylate the next protein in the pathway. A chain of reactions leads to some metabolic change. The substrates for protein kinases are different in various cell types, so the effect of cAMP varies. In skeletal muscle cells, a protein kinase triggers the breakdown of glycogen to glucose, whereas in cells of the hypothalamus, a protein kinase activates the gene that encodes a growth-inhibiting hormone.

Recall from Chapter 6 that some G proteins use phospholipids as second messengers. Certain hormone-receptor complexes activate a G protein that then activates phospholipase C, a membrane-bound enzyme (see Fig. 6-9). This enzyme splits a membrane phospholipid into two products:

inositol trisphosphate (IP_3) and *diacylglycerol* (DAG). Both act as second messengers. DAG (in combination with calcium ions) activates a protein kinase that phosphorylates a variety of proteins, and IP_3 opens calcium channels in the endoplasmic reticulum, releasing calcium ions into the cytosol. Calcium ions bind to certain proteins, such as *calmodulin*. The activated calmodulin then activates other proteins.

Enzyme-linked receptors function directly Enzyme-linked receptors are transmembrane proteins with a hormone-binding site outside the cell and an enzyme site inside the cell (see Fig. 6-5c). These receptors are not linked to G proteins. They function directly as enzymes or are directly linked to enzymes. Most enzyme-linked receptors are **tyrosine kinase receptors** that bind growth factors and other signal molecules, including insulin. When the receptor is activated, it phosphorylates the amino acid tyrosine in specific signaling proteins inside the cell.

CHECKPOINT 49.3

- **CONNECT** What are the roles of receptors and second messengers in hormone action?
- How do steroid and peptide hormones differ in their mechanisms of action?
- What is the mechanism of action of a hormone that uses cyclic AMP as a second messenger?

49.4 Neuroendocrine Regulation in Invertebrates

LEARNING OBJECTIVE

- 6 Identify four functions of invertebrate neurohormones and describe the regulation of insect development.

Among invertebrates, hormones are secreted mainly by neurons rather than by endocrine glands. These *neurohormones* regulate regeneration in hydras, flatworms, and annelids as well as color changes in crustaceans. Invertebrate neurohormones regulate growth, development, metabolism, gamete production, and reproduction (including reproductive behavior) in many groups. Trends in the evolution of invertebrate endocrine systems include an increasing number of both neurohormones and hormones secreted by endocrine glands and a greater role of hormones in physiological processes.

Insects have endocrine glands and neuroendocrine cells. Their various hormones and neurohormones interact with one another to regulate metabolism, growth, and development, including molting and metamorphosis. Hormonal control of development in insects varies among species. Generally, some environmental factor (e.g., temperature change) activates neuroendocrine cells in the brain. These cells then produce a neurohormone referred to as *brain hormone (BH)*, which is transported down axons and stored in the paired *corpora cardiaca* (sing., *corpus cardiacum*; FIG. 49-6). When released from the corpora cardiaca, BH stimulates the *prothoracic glands*, endocrine glands in the prothorax, to produce *molting hormone (MH)*, also called *ecdysone* (see Fig. 49-2b). MH is a steroid hormone that stimulates growth and molting.

In the immature insect, paired endocrine glands called *corpora allata* (sing., *corpus allatum*) secrete *juvenile hormone (JH)*. This hormone suppresses metamorphosis at each larval molt so that the insect increases in size while remaining in its immature state. After the molt, the insect is still in a larval stage. When the concentration of JH decreases below some critical level, metamorphosis occurs, and the insect is transformed into a pupa (see Chapter 31). In the absence of JH, the pupa molts and becomes an adult. The nervous system regulates the secretory activity of the corpora allata, and the amount of JH decreases with successive molts.

CHECKPOINT 49.4

- What are four actions of hormones in invertebrates?
- **CONNECT** How does juvenile hormone affect metamorphosis in insects?

49.5 Endocrine Regulation in Vertebrates

LEARNING OBJECTIVES

- 7 Identify the classical vertebrate endocrine glands and describe the actions of their hormones; describe the effects of hypersecretion and hyposecretion on homeostasis.
- 8 Describe the mechanisms by which the hypothalamus and pituitary gland integrate regulatory functions; summarize the actions of the hypothalamic and pituitary hormones.
- 9 Describe the actions of the thyroid and parathyroid hormones, their regulation, and the effects of malfunction.
- 10 Contrast the actions of insulin and glucagon, and describe diabetes mellitus and hypoglycemia, including the metabolic effects of these disorders.
- 11 Describe the actions and regulation of the adrenal hormones, including their role in the body's response to stress.

Vertebrate hormones regulate such diverse activities as growth and development, reproduction, metabolic rate, fluid balance, blood homeostasis, and response to stress. Most vertebrates have similar endocrine glands, although the actions of some hormones may be different in various vertebrate groups. TABLE 49-1 gives the sources, target tissues, and principal physiological actions of some of the major vertebrate hormones. The hypothalamus and pituitary gland regulate many of these hormones. The principal human endocrine glands are illustrated in FIGURE 49-7.

Homeostasis depends on normal concentrations of hormones

When a disorder or disease process affects an endocrine gland, the rate of secretion may become abnormal. If **hyposecretion**, abnormally reduced output, occurs, target cells are deprived of needed stimulation. If **hypersecretion**, abnormally increased output, occurs, the target cells may be overstimulated. In some endocrine disorders, an appropriate amount of hormone is secreted, but the target cell receptors do not function properly. As a result, the target cells cannot respond to the hormone. These failures in regulation threaten homeostasis and can lead to predictable metabolic malfunctions and clinical symptoms (TABLE 49-2).

The hypothalamus regulates the pituitary gland

Most endocrine activity is controlled directly or indirectly by the **hypothalamus**, which links the nervous and endocrine

FIGURE 49-6 Regulation of growth and molting in insects

Hormones regulate insect development. Most insects go through a series of larval stages and then undergo metamorphosis to the adult form. This dissection of an insect head shows the brain, paired corpora allata, and paired corpora cardiaca.

systems both anatomically and physiologically. The **pituitary gland** is connected to the hypothalamus by the pituitary stalk. The hypothalamus receives input from other areas of the brain and from hormones in the blood. In response, neurons of the hypothalamus secrete neurohormones that regulate specific physiological processes.

Because secretions of the pituitary gland control the activities of several other endocrine glands, biologists sometimes refer to it as the master gland of the body. Although it is the size of a large pea and weighs only about 0.5 g (0.02 oz), the pituitary gland produces six peptide hormones that exert far-reaching influence over growth, metabolism, reproduction, and many other body activities. The human pituitary gland consists of two main parts: the *anterior pituitary* and the *posterior pituitary*. In some vertebrates, an intermediate lobe is present.

The posterior pituitary gland releases hormones produced by the hypothalamus

The **posterior pituitary**, also called the posterior lobe of the pituitary gland, develops from brain tissue. This neuroendocrine organ *secretes* two peptide hormones, **oxytocin** and **antidiuretic hormone (ADH)**, also known as *vasopressin*. Oxytocin and ADH are actually *produced* by neuroendocrine cells in two distinct areas of the hypothalamus. These

- 1 Neuroendocrine cells secrete brain hormone (BH), which is stored in corpora cardiaca.
- 2 When released, BH stimulates prothoracic glands to secrete molting hormone (MH), which stimulates growth and molting.
- 3 In immature insect, corpora allata secrete juvenile hormone (JH), which suppresses metamorphosis at each larval molt.
- 4 Metamorphosis to adult form occurs when MH acts in absence of JH.

hormones are enclosed within vesicles and transported down the axons of the neuroendocrine cells into the posterior pituitary gland (FIG. 49-8 on page 1062). The vesicles are stored in the axon terminals until the neuron is stimulated. Then the hormones are released and diffuse into surrounding capillaries.

We discussed the function of ADH in Chapter 48. Recall that ADH stimulates reabsorption of water in the kidneys. Oxytocin concentration in the blood rises toward the end of pregnancy, stimulating the strong contractions of the uterus needed to expel a baby. Synthetic oxytocin is sometimes administered clinically to initiate or speed labor.

After birth, when an infant sucks at its mother's breast, sensory neurons signal the pituitary to release oxytocin. The hormone stimulates contraction of smooth muscle cells surrounding the milk glands so that milk is let down into the ducts, making it available to the nursing infant. Because oxytocin also stimulates the uterus to contract, breast-feeding promotes recovery of the uterus to non-pregnant size.

Oxytocin also plays a role in social behavior. In voles, for example, males with higher concentrations of oxytocin are more likely to be monogamous (have a single sexual partner) than those with lower concentrations. In humans, oxytocin affects maternal behavior. Of critical importance, this hormone facilitates attachment between mother and infant. It appears that oxytocin continues to play a role in social behavior throughout the lifespan. This hormone appears to help us recognize familiar faces and promote trust and cooperation. Oxytocin may also help us notice social cues.

Oxytocin also plays a role in social behavior. In voles, for example, males with higher concentrations of oxytocin are more likely to be monogamous (have a single sexual partner) than those with lower concentrations. In humans, oxytocin affects maternal behavior. Of critical importance, this hormone facilitates attachment between mother and infant. It appears that oxytocin continues to play a role in social behavior throughout the lifespan. This hormone appears to help us recognize familiar faces and promote trust and cooperation. Oxytocin may also help us notice social cues.

The anterior pituitary gland regulates growth and other endocrine glands

The **anterior pituitary**, also called the anterior lobe of the pituitary, develops from epithelial cells rather than neural cells. The anterior pituitary functions like a classical endocrine gland: it receives signals by way of the blood and releases its hormones into the blood. The hypothalamus produces several **releasing hormones** and **inhibiting hormones** that regulate the production and secretion of specific hormones by the anterior pituitary.

Table 49-1 Some Vertebrate Endocrine Glands and Their Hormones

Gland	Hormone	Target Tissue	Principal Actions
Hypothalamus	Releasing and inhibiting hormones	Anterior pituitary	Regulate secretion of hormones by the anterior pituitary
Posterior pituitary (storage and release of hormones produced by hypothalamus)	Oxytocin	Uterus	Stimulates contraction
	Antidiuretic hormone (ADH)	Mammary glands Kidneys (collecting ducts)	Stimulates ejection of milk into ducts Stimulates reabsorption of water
Anterior pituitary	Growth hormone (GH)	General	Stimulates growth of skeleton and muscle
	Prolactin	Mammary glands	Stimulates milk production
	Melanocyte-stimulating hormones (MSH); belong to a group of hormones known as melanocortins	Pigment cells in skin	Stimulate melanin production in some animals; in humans, help regulate food intake
	Thyroid-stimulating hormone (TSH)	Thyroid gland	Stimulates secretion of thyroid hormones; helps regulate bone remodeling
	Adrenocorticotrophic hormone (ACTH)	Adrenal cortex	Stimulates secretion of adrenal cortical hormones
	Gonadotropic hormones* (follicle-stimulating hormone [FSH]; luteinizing hormone [LH])	Gonads	Stimulate gonad function and growth
Thyroid gland	Thyroxine (T_4) and triiodothyronine (T_3)	General	Stimulate metabolic rate; regulate energy metabolism
	Calcitonin	Bone	Decreases blood calcium concentration
Parathyroid glands	Parathyroid hormone	Bone, kidneys, digestive tract	Increases blood calcium concentration
Pancreas	Insulin	General	Decreases blood glucose concentration
	Glucagon	Liver, adipose tissue	Increases blood glucose concentration
Adrenal medulla	Epinephrine and norepinephrine	Muscle; blood vessels; liver; adipose tissue	Help body cope with stress; increase metabolic rate; increase blood glucose concentration; increase heart rate and blood pressure
Adrenal cortex	Mineralocorticoids	Kidney tubules	Maintain sodium and potassium balance
	Glucocorticoids	General	Help body cope with long-term stress; increase blood glucose concentration
Pineal gland	Melatonin	Hypothalamus	Regulates biological rhythms
Ovary*	Estrogens	General; uterus	Develop and maintain sex characteristics in females; stimulate growth of uterine lining
	Progesterone	Uterus; breast	Stimulates development of uterine lining
Testis*	Testosterone	General; reproductive structures	Develops and maintains sex characteristics in males; promotes spermatogenesis

* Reproductive hormones are discussed in Chapter 50; see Tables 50-1 and 50-2.

Releasing and inhibiting hormones are produced by specific endocrine cells in the hypothalamus and are stored in vesicles in the axon terminals. When signaled to do so, the cells secrete a particular releasing (or inhibiting) hormone, which then enters a capillary. The hormone is transported in the blood through special portal veins that connect the hypothalamus with the anterior lobe of the pituitary. Within the anterior pituitary, the portal veins divide into a second set of capillaries. Thus, these portal veins, like the hepatic portal vein, do not deliver blood to a larger vein directly; they connect two sets of capillaries.

Releasing and inhibiting hormones pass through the capillary walls into the tissue of the anterior lobe of the pituitary. These hormones control the secretion of anterior pituitary hormones. For example, when the body is stressed, the hypothalamus secretes *corticotropin-releasing factor*. This releasing factor stimulates the anterior pituitary to secrete *adrenocorticotrophic hormone (ACTH)*.

The anterior lobe secretes prolactin, melanocyte-stimulating hormones, growth hormone, and several **tropic hormones** that stimulate other endocrine glands (**FIG. 49-9**). **Prolactin** stimulates the cells of the mammary glands to produce milk in a nursing mother. This hormone has diverse roles in various vertebrate groups. In fishes and amphibians, for example, it helps maintain water and electrolyte balance by decreasing Na^+ and K^+ loss in the urine. Prolactin also inhibits metamorphosis in amphibians and stimulates molting in reptiles. This versatile hormone appears to have a role in immune function and in the formation of new blood vessels.

Melanocyte-stimulating hormones (MSH) (a group of **melanocortins**; see Chapter 47) are a group of peptide hormones secreted by the anterior pituitary gland and also by certain neurons in the hypothalamus. In some fishes, amphibians, and reptiles, MSH causes the skin to darken, facilitating camouflage. In

Figure 49-7 The principal human endocrine glands
Many of the hormones produced by these glands and their actions are discussed in this chapter.

humans, it suppresses appetite, leading to weight loss, and thus is important in regulating body weight and energy.

Growth hormone stimulates protein synthesis Whether someone is tall or short depends on many factors, including genes, diet, and hormone balance. **Growth hormone** (also

called *somatotropin*) is referred to as an **anabolic hormone** because it promotes tissue growth. (The general acronym for vertebrate growth hormone is GH; human growth hormone is referred to as HGH or hGH.) Many of the effects of GH on skeletal growth are indirect. GH stimulates liver cells (and cells of many other tissues) to produce peptides called **insulin-like growth factors (IGFs)**. These growth factors (1) promote the linear growth of the skeleton by stimulating cartilage formation in growth areas of bones and (2) promote protein synthesis and other anabolic processes, which stimulates general tissue growth and increases organ size.

In adults as well as in growing children, GH is secreted in pulses throughout the day. The hypothalamus regulates GH secretion by secreting a **growth hormone–releasing hormone (GHRH)** and a **growth hormone–inhibiting hormone (GHIH)**, which is also called *somatostatin*. A high level of GH in the blood signals the hypothalamus to secrete GHIH; in response, the pituitary slows its release of GH. In contrast, a low level of GH in the blood stimulates the hypothalamus to secrete GHRH, which stimulates the pituitary gland to release more GH. Many other factors, including blood sugar level, amino acid concentration, and stress, influence GH secretion.

For children to grow, research supports the age-old notions that they need plenty of sleep, a proper diet, and regular exercise. GH is secreted about 1 hour after the onset of deep sleep and in a series of pulses 2 to 4 hours after a meal. Secretion of GH increases during exercise, probably because rapid metabolism by muscle cells lowers the blood glucose level.

Emotional support is also necessary for proper growth. Growth is retarded in children who are deprived of cuddling, playing, and other forms of nurture, even when their needs for food and shelter are met. In extreme cases, childhood stress can produce a form of retarded development known as *psychosocial dwarfism*. Some emotionally deprived children exhibit abnormal sleep patterns, which may be the basis for decreased secretion of GH.

Other hormones also influence growth. Thyroid hormones appear necessary for normal GH secretion and function and for normal tissue response to IGFs. Sex hormones must be present for the adolescent growth spurt to occur. However, the presence of sex hormones eventually causes the growth centers within the long bones to ossify so that no further increase in height can occur even when GH is present.

Table 49-2 Consequences of Endocrine Malfunction

Hormone	Hyposecretion	Hypersecretion
Growth hormone	Pituitary dwarfism	Gigantism if malfunction occurs in childhood; acromegaly in adult
Thyroid hormones	Cretinism (in children); myxedema, a condition of pronounced adult hypothyroidism; dietary iodine deficiency leads to hyposecretion and goiter	Hyperthyroidism; increased metabolic rate, nervousness, irritability; goiter; Graves' disease
Parathyroid hormone	Spontaneous discharge of nerves; spasms; tetany; death	Weak, brittle bones; kidney stones
Insulin	Diabetes mellitus	Hypoglycemia
Hormones of adrenal cortex	Adrenal insufficiency (Addison's disease)	Cushing's syndrome

Figure 49-8 Synthesis and secretion of posterior pituitary hormones

Neuroendocrine cells in the hypothalamus manufacture antidiuretic hormone (ADH) and oxytocin. These hormones are packaged in vesicles. The axons of the neuroendocrine cells extend into the posterior pituitary. The vesicles containing the hormones are transported through the axons and stored in the axon ends. When needed, the hormones are secreted by the posterior lobe of the pituitary gland. The hormones enter the blood, and are transported by the circulatory system.

Inappropriate amounts of growth hormone secretion result in abnormal growth

Have you ever wondered why some people fail to grow normally? Extreme deficiency in GH during childhood causes pituitary dwarfism. This condition is usually caused by insufficient production of GH by the pituitary gland. However, dwarfism also occurs when the liver produces insufficient IGF or when target tissues do not respond to IGF. Although miniature, a pituitary dwarf has normal intelligence and is usually well-proportioned. If the growth centers in the long bones are still active when this condition is diagnosed, it can often be effectively treated by HGH injection. Human GH can be synthesized by recombinant DNA technology.

A person grows abnormally tall when the anterior pituitary secretes excessive amounts of HGH during childhood. This condition is called **gigantism**. If hypersecretion of HGH occurs during adulthood, the individual cannot grow taller. Instead, connective tissue thickens, and bones in the hands, feet, and face may increase in diameter. This condition is known as **acromegaly** (*acromegaly* means “large extremities”).

Thyroid hormones increase metabolic rate

The **thyroid gland** is located in the neck region, in front of the trachea and below the larynx. The **thyroid hormones—thyroxine**,

Figure 49-9 Synthesis and secretion of anterior pituitary hormones

The hypothalamus secretes several specific releasing and inhibiting hormones. The hormones are transported to the anterior lobe of the pituitary gland by way of portal veins. These regulatory hormones stimulate or inhibit the release of specific hormones by cells of the anterior pituitary. The anterior pituitary hormones act on a wide variety of target tissues. (ACTH, adrenocorticotrophic hormone)

also known as T_4 , and **triiodothyronine**, or T_3 —are synthesized from the amino acid tyrosine and iodine. Thyroxine has four iodine atoms attached to each molecule, and T_3 has three. In most target

tissues, T_4 is converted to T_3 , the more active form (see Fig. 49-2c). We describe the actions of calcitonin, another hormone secreted by the thyroid gland, when we discuss the parathyroid glands.

In vertebrates, thyroid hormones are essential for normal growth and development. These hormones increase the rate of metabolism in most body tissues. After T_3 binds with its receptor in the nucleus of a target cell, the T_3 receptor complex induces or suppresses synthesis of specific enzymes and other proteins. Thyroid hormones also help regulate the synthesis of proteins necessary for cell differentiation. For example, tadpoles cannot develop into adult frogs without thyroxine.

Negative feedback systems regulate thyroid secretion

The regulation of thyroid hormone secretion depends on a negative feedback loop between the anterior pituitary and the thyroid gland (FIG. 49-10). When the concentration of thyroid hormones in the blood rises above normal, the anterior pituitary secretes less **thyroid-stimulating hormone (TSH)**:

thyroid hormone concentration high → inhibits anterior pituitary → secretes less TSH → thyroid gland secretes less hormone → homeostasis

When the concentration of thyroid hormones decreases, the anterior pituitary secretes more TSH. TSH acts by way of cAMP to promote synthesis and secretion of thyroid hormones and also to promote increased size of the thyroid gland itself. The effect of TSH can be summarized as follows:

thyroid hormone concentration low → anterior pituitary secretes more TSH → thyroid gland secretes more hormone → homeostasis

In some mammals, changes in weather affect the hypothalamus. Exposure to very cold temperature stimulates the hypothalamus to increase secretion of **TSH-releasing hormone (TRH)**. This action causes a dramatic increase in thyroid hormone secretion. Metabolic rate increases, which also increases heat production, so the body temperature rises. Increased body temperature has a negative feedback effect, limiting further secretion of thyroid hormones.

Malfunction of the thyroid gland leads to specific disorders Extreme hypothyroidism during infancy and childhood results in low metabolic rate and can lead to **cretinism**, a condition characterized by intellectual disability and impaired physical development. When diagnosed early enough, hypothyroidism can be treated with thyroid hormones, and cretinism can be prevented.

An adult who feels like sleeping all the time, has little energy, and is mentally slow or confused may be suffering from hypothyroidism. When there is almost no thyroid function, the basal metabolic rate is reduced by about 40% and the patient develops **myxedema**, characterized by a slowing down of physical and mental activity. Hypothyroidism is treated by oral administration of the missing hormone.

Figure 49-10 Regulation of thyroid hormone secretion

Hyperthyroidism does not cause abnormal growth but does increase metabolic rate by 60% or even more. This increase in metabolism results in the rapid use of nutrients, causing the individual to be hungry and to eat more. Increased food intake is not sufficient to meet the demands of the rapidly metabolizing cells, however, and people with this condition often lose weight. They also tend to be nervous, irritable, and emotionally unstable. The most common form of hyperthyroidism is **Graves' disease**, an autoimmune disease. Abnormal antibodies bind to TSH receptors and activate them. Production of thyroid hormones increases.

An abnormal enlargement of the thyroid gland, or **goiter**, may be associated with either hypersecretion or hyposecretion (see Fig. 49-10b). In Graves' disease the abnormal antibodies that activate TSH receptors can cause the development of a goiter. Worldwide, more than 90% of goiters are caused by iodine deficiency. Without iodine the gland cannot make thyroid hormones, resulting in hyposecretion. When the concentration of thyroid hormones in the blood decreases, the anterior pituitary secretes large amounts of TSH. The TSH stimulates growth of

the thyroid gland, sometimes to gigantic proportions. However, enlargement of the gland does not increase production of the hormones because the needed ingredient—iodine—is still missing.

Seafood is a rich source of iodine, and iodine is also added to table salt as a nutritional supplement. In fact, thanks to iodized salt, goiter is no longer common in the United States and other highly developed countries. In other parts of the world, however, hundreds of thousands of people still suffer from this easily preventable disorder. Because it results in hypothyroidism, iodine deficiency has a negative effect on intellectual and physical development. *Lancet*, a well-respected British medical journal, has referred to iodine deficiency as “the single greatest preventable cause of mental retardation.”

The parathyroid glands regulate calcium concentration

The **parathyroid glands** are typically embedded in the connective tissue surrounding the thyroid gland. These glands secrete **parathyroid hormone (PTH)**, a polypeptide that helps regulate the calcium level of the blood and interstitial fluid (FIG. 49-11a). Parathyroid hormone acts by way of a G protein–linked receptor and cAMP to stimulate calcium release from bones and to increase calcium reabsorption from

the kidney tubules. It also activates vitamin D, which then increases the amount of calcium absorbed from the intestine.

Calcitonin, a peptide hormone secreted by the thyroid gland, works antagonistically to parathyroid hormone (FIG. 49-11b). When the concentration of calcium rises above homeostatic levels, calcitonin is released and rapidly inhibits removal of calcium from bone.

The islets of the pancreas regulate blood glucose concentration

In addition to secreting digestive enzymes (see Chapter 47), the pancreas is an important endocrine gland. Its hormones, insulin and glucagon, are secreted by cells that occur in little clusters, the **islets of Langerhans**, throughout the pancreas (FIG. 49-12). About one million islets are present in the human pancreas. They consist mainly of **beta cells**, which secrete insulin, and **alpha cells**, which secrete glucagon.

Insulin lowers the concentration of glucose in the blood

Insulin is an anabolic hormone that regulates the use and storage of nutrients. Insulin stimulates cells of many tissues, including liver, muscle, and fat cells, to take up glucose from the blood by facilitated diffusion (see Chapter 5). Once glucose enters muscle cells, it is either used immediately as

(a) Calcium concentration too low. When calcium concentration decreases below the normal range, the parathyroid glands secrete parathyroid hormone (PTH). PTH stimulates homeostatic mechanisms that restore appropriate calcium concentration.

(b) Calcium concentration too high. When calcium concentration increases above its set point, the parathyroid glands are inhibited. The thyroid gland secretes calcitonin, which inhibits Ca^{2+} release from bone and decreases Ca^{2+} reabsorption in the kidneys.

Figure 49-11 Regulation of calcium homeostasis

Green arrows indicate stimulation; red arrows indicate inhibition.

Figure 49-12 An islet of Langerhans in the pancreas

Scattered throughout the pancreas, clusters of endocrine cells (such as the one shown in this LM) secrete insulin and glucagon.

fuel or stored as glycogen. Insulin also inhibits liver cells from releasing glucose. Thus, insulin activity *lowers* the glucose level in the blood.

Insulin also helps regulate fat and protein metabolism. It reduces the use of fatty acids as fuel and instead stimulates their storage in adipose tissue. Insulin has an anabolic effect on protein metabolism, resulting in a net increase in protein in cells. It promotes protein synthesis by increasing the number of amino acid transporters in the plasma membrane, thus stimulating the transport of certain amino acids into cells. Insulin also promotes transcription and translation.

Glucagon raises the concentration of glucose in the blood The effects of **glucagon** are opposite to those of insulin. Glucagon's main action is to raise blood glucose level. It does so by stimulating liver cells to convert glycogen to glucose. Glucagon also stimulates *gluconeogenesis*

(glu-ko-nee-oh-gen'-eh-sis), the production of glucose from noncarbohydrates. Glucagon mobilizes fatty acids by promoting breakdown of fat and inhibiting triacylglycerol synthesis. This hormone also stimulates the liver to degrade proteins and inhibits protein synthesis.

Glucose concentration regulates insulin and glucagon secretion The concentration of glucose in the blood directly controls insulin and glucagon secretion (**FIG. 49-13**). After a meal, when the blood glucose level rises as a result of intestinal absorption, beta cells are stimulated to increase insulin secretion. Then, as cells remove glucose from the blood, decreasing its concentration, insulin secretion decreases.

high blood glucose concentration → beta cells secrete insulin → blood glucose concentration decreases → homeostasis

Key Point

Insulin and glucagon work antagonistically to regulate the concentration of glucose in the blood.

Figure 49-13 Regulation of blood glucose concentration

When the concentration of glucose in the blood increases above normal, beta cells secrete insulin. This hormone lowers blood glucose concentration, thus restoring homeostasis. When the concentration of glucose in the blood decreases below normal, alpha cells secrete glucagon. This hormone increases blood glucose concentration, restoring homeostasis.

PREDICT What would happen if an autoimmune disease sharply reduced the number of functional alpha cells?

When you have not eaten for several hours, the concentration of glucose in your blood begins to fall. When it decreases from its normal fasting level of about 90 mg of glucose per 100 mL of blood to about 70 mg of glucose, the alpha cells of the islets increase their secretion of glucagon. Glucose is mobilized from storage in the liver cells, returning blood glucose concentration to normal:

low blood glucose concentration → alpha cells secrete glucagon
→ blood glucose concentration increases → homeostasis

Alpha cells respond to the glucose concentration within their own cytoplasm, which reflects the blood glucose level. When blood glucose level is high, there is generally a high level of glucose within the alpha cells, and glucagon secretion is inhibited.

Note that in these negative feedback systems, insulin and glucagon work antagonistically to keep blood glucose concentration within homeostatic limits. When the glucose level rises, insulin release brings it back to normal; when the glucose concentration falls, glucagon acts to raise it again. The insulin-glucagon system is a powerful, fast-acting mechanism for keeping blood glucose level within normal limits. Why is it important to maintain a constant blood glucose level? Recall that brain cells ordinarily are unable to use other nutrients as fuel, so they depend on a continuous supply of glucose. As we will discuss, several other hormones also affect blood glucose concentration.

Diabetes mellitus is a serious disorder of carbohydrate metabolism Diabetes mellitus, the most common endocrine disorder, is a serious health problem, and according to the World Health Organization, its global prevalence is increasing rapidly. More than 422 million people worldwide have this disorder. (Note that diabetes mellitus is an entirely different disorder from diabetes insipidus, which was discussed in Chapter 48.) According to the Centers for Disease Control and Prevention (CDC), diabetes is the leading cause of kidney failure, nontraumatic lower limb amputations, and new cases of blindness. Diabetes is also a major risk factor for cardiovascular disease, neurological disease, and premature death. Approximately one-half of the people suffering from diabetes are unaware that they have this disorder; consequently, they do not receive treatment and are at high risk for its serious effects.

Diabetes mellitus is actually a group of related disorders characterized by high blood glucose concentrations. Two main types of diabetes are type 1 and type 2. *Type 1 diabetes* is an autoimmune disease in which antibodies mark the beta cells for destruction. T cells destroy the beta cells, resulting in insulin deficiency. Insulin injections are needed to correct the carbohydrate imbalance that results. This disorder usually develops before age 30, often during childhood. Type 1 diabetes is caused by a combination of genetic predisposition and environmental factors, possibly including infection by a virus.

More than 90% of diabetics have *type 2 diabetes*. This disorder develops gradually, typically in overweight people. **Metabolic syndrome** often precedes type 2 diabetes. The symptoms of metabolic syndrome include obesity, large waist circumference (“apple shape”), elevated blood glucose concentration, high triacylglycerol (triglyceride) and low HDL (“good” cholesterol) concentrations in the blood, and high blood pressure.

More than 20% of obese children have impaired glucose tolerance, an early warning sign of diabetes. Impaired glucose tolerance, which affects more than 200 million people worldwide, is defined as *hyperglycemia* (a blood glucose concentration that is abnormally high) following ingestion of a large amount of glucose (a glucose load).

Type 2 diabetes typically begins as **insulin resistance**, a condition in which cells cannot use insulin effectively. In type 2 diabetes, normal (or greater than normal) concentrations of insulin are present in the blood, but target cells cannot use it. You can decrease your risk of type 2 diabetes with a healthy diet, regular physical activity (at least 30 minutes of moderate-intensity exercise each day), and by avoiding tobacco use.

Similar metabolic disturbances occur in both types of diabetes mellitus: disruption of carbohydrate, fat, and protein metabolism and electrolyte imbalance.

1. *Glucose use decreases.* In a diabetic, the cells have difficulty taking up glucose from the blood, and its accumulation causes hyperglycemia. Instead of the normal fasting concentration of about 90 mg of glucose per 100 mL of blood, the level may exceed 140 mg per 100 mL and may reach concentrations of more than 500 mg per 100 mL. Recall from Chapter 48 that when glucose concentration exceeds its **tubular transport maximum (T_m)**, the maximum rate at which it can be reabsorbed, glucose is excreted in the urine. Despite the large quantities of glucose in the blood, insulin-dependent cells in a diabetic can take in only about 25% of the glucose they require for fuel.
2. *Fat mobilization increases.* Cells turn to fat and protein for energy. The absence of insulin promotes the mobilization of fat stores to provide nutrients for cellular respiration. Unfortunately, however, the blood lipid level may reach five times the normal level, leading to the development of atherosclerosis (see Chapter 44). Increased fat metabolism also increases the formation of ketone bodies, which build up in the blood. This accumulation can cause *ketoacidosis*, a condition in which the body fluids and blood become too acidic. When the ketone level in the blood rises, ketones appear in the urine, another clinical indication of diabetes mellitus. If severe, ketoacidosis can lead to coma and death.
3. *Protein use increases.* Lack of insulin also results in increased protein breakdown relative to protein synthesis, so the untreated diabetic becomes thin and emaciated.
4. *Electrolyte imbalance.* When ketone bodies and glucose are excreted in the urine, water follows by osmosis; as a result, urine volume increases. The resulting dehydration causes thirst and challenges electrolyte homeostasis. When ketones are excreted, they also take sodium, potassium, and some other cations with them, contributing to electrolyte imbalance.

Many type 2 diabetics can keep their blood glucose levels within normal range by diet management, weight loss, and regular exercise. When this treatment approach is not

effective, the disorder is treated with oral drugs that stimulate insulin secretion and promote its actions. Approximately one-third of type 2 diabetics eventually need insulin injections.

The dramatic increase in type 2 diabetes is a public health problem resulting from increased prevalence of obesity, rapid increases in people becoming overweight, and lack of physical activity. Because type 2 diabetes is associated with insulin resistance, researchers are studying this metabolic problem in their search for causes of and cures for diabetes. Researchers have found a strong association between increased fat tissue and insulin resistance. When insulin-resistant individuals lose weight, they become more sensitive to insulin.

In hypoglycemia the blood glucose concentration is too low Low blood glucose concentration, or *hypoglycemia*, sometimes occurs in people who later develop diabetes. These individuals may have impaired glucose tolerance in which the islets overreact to glucose challenge. When carbohydrates are ingested, there is a delayed insulin response, followed after about 3 hours by too much insulin secretion. This hypersecretion causes glucose levels to fall, and the individual feels drowsy. If this reaction is severe, the person may become uncoordinated or even unconscious.

Serious hypoglycemia can develop if diabetics receive injections of too much insulin or if the islets, because of a tumor, secrete too much insulin. The blood glucose concentration may then fall drastically, depriving brain cells of their needed fuel supply. These events can lead to **insulin shock**, a condition in which the patient may appear drunk or may become unconscious, suffer convulsions, and even die.

The adrenal glands help the body respond to stress

The paired **adrenal glands** are small, yellow masses of tissue that lie in contact with the upper ends of the kidneys (**FIG. 49-14**). Each gland consists of a central portion, the **adrenal medulla**, and a larger outer section, the **adrenal cortex**. Although joined anatomically, the adrenal medulla and cortex develop from different types of tissue in the embryo and function as distinctly different glands. However, both secrete hormones that help regulate metabolism and help the body respond to stress.

The adrenal medulla initiates an alarm reaction The adrenal medulla is a neuroendocrine gland that is coupled to the sympathetic nervous system. It develops from neural tissue, and its secretion is controlled by sympathetic nerves. The adrenal medulla secretes **epinephrine** and **norepinephrine**. Chemically, these hormones are very similar; they are amino acid derivatives that belong to the chemical group known as **catecholamines** (see Fig. 49-2c). Most of the hormone output of the adrenal medulla is epinephrine. Recall that

Figure 49-14 Adrenal gland

The adrenal glands are located above the kidneys. Each gland consists of a central adrenal medulla surrounded by an adrenal cortex.

norepinephrine also serves as a neurotransmitter released by sympathetic neurons and by some neurons in the central nervous system (see Chapter 41).

Under normal conditions, the adrenal medulla continuously secretes small amounts of both epinephrine and norepinephrine. Their secretion is under neural control. When anxiety is aroused, the hypothalamus sends signals via sympathetic nerves to the adrenal medulla. Sympathetic neurons release acetylcholine, which triggers the adrenal medulla to release larger amounts of epinephrine and norepinephrine.

During a stressful situation, adrenal medullary hormones initiate an *alarm reaction* that enables you to think more quickly, fight harder, or run faster than usual. Metabolic rate increases by as much as 100%. Blood is rerouted to those organs essential for emergency action (**FIG. 49-15**). Blood vessels going to the brain, muscles, and heart are dilated, whereas those to the skin and kidneys are constricted. Constriction of blood vessels serving the skin has the added advantage of decreasing blood loss in case of hemorrhage (and explains the sudden paling that comes with fear). At the same time, the heart beats faster. Strength of muscle contraction increases. Thresholds in the reticular activating system of the brain are lowered, so you become more alert (see Chapter 42). The adrenal medullary hormones also raise fatty acid and glucose levels in the blood, ensuring needed fuel for extra energy.

The adrenal cortex helps the body deal with chronic stress The adrenal cortex synthesizes steroid hormones from cholesterol (which in turn is made in the liver from acetyl coenzyme A). Although the adrenal cortex produces more than 30 types of steroids, it secretes only three types of hormones in significant amounts: sex hormone precursors, mineralocorticoids, and glucocorticoids.

In both sexes the adrenal cortex secretes sex hormone precursors, such as androgens (masculinizing hormones). Certain tissues convert sex hormone precursors to **testosterone**, the principal male sex hormone, and **estradiol**, the principal female sex hormone. In males, androgen production by the adrenal cortex is not significant because the testes produce testosterone. However, in females, the adrenal cortex secretes the androgen used to produce most of the testosterone circulating in the blood.

The principal **mineralocorticoid** is **aldosterone**. (Recall from Chapter 48 that aldosterone helps regulate fluid balance by regulating salt balance.) In response to aldosterone, the kidneys reabsorb more sodium and excrete more potassium. As a result of increased sodium, extracellular fluid volume increases, which results in greater blood volume and elevated blood pressure.

When the adrenal glands do not produce enough aldosterone, large amounts of sodium are excreted in the urine. Water leaves the body with the sodium (because of osmotic pressure), and the blood volume may be so markedly reduced that the patient dies of low blood pressure.

Cortisol, also called *hydrocortisone*, accounts for about 95% of the **glucocorticoid** activity of the human adrenal cortex (see Fig. 49-2b). Cortisol helps ensure adequate fuel supplies for the cells when the body is under stress. Its principal action is to stimulate production of glucose from other nutrients in liver cells.

Cortisol helps provide nutrients for glucose production by stimulating amino acid transport into liver cells (see Fig. 49-15). It also promotes mobilization of fats so that glycerol from triacylglycerol molecules is available for conversion to glucose. These actions ensure that glucose and glycogen are produced in the liver, and the concentration of glucose in the blood rises. Thus, the adrenal cortex provides an important backup system for the adrenal medulla, ensuring adequate glucose supplies when the body is under stress and in need of extra energy.

During stress, the brain and the adrenal glands work together to help the body respond effectively (see Fig. 49-15; also see *Inquiring About: The Neurobiology of Traumatic Experience* in Chapter 42). Almost any type of stress stimulates the hypothalamus to secrete **corticotropin-releasing factor (CRF)**, which stimulates the anterior pituitary to secrete **adrenocorticotrophic hormone (ACTH)**. ACTH regulates both glucocorticoid and aldosterone secretion. It is so potent that it can result in a 20-fold increase in cortisol secretion within minutes. When the body is not under stress, high levels of cortisol in the blood inhibit both CRF secretion by the hypothalamus and ACTH secretion by the pituitary.

Figure 49-15 Response to stress

The adrenal glands release hormones that prepare the body to respond to stressful experiences. (RAS, reticular activating system; CRF, corticotropin-releasing factor; ACTH, adrenocorticotrophic hormone)

Glucocorticoids are used clinically to reduce inflammation in allergic reactions, infections, arthritis, and certain types of cancer. These hormones inhibit production of prostaglandins (which are mediators of inflammation). Glucocorticoids also reduce inflammation by decreasing capillary permeability, which reduces swelling. In addition, they reduce the effects of histamine and so are used to treat allergic symptoms.

When used in large amounts over long periods, glucocorticoids can cause serious side effects. Although they help stabilize lysosome membranes so that they do not destroy tissues with their potent enzymes, the ability of lysosomes to degrade foreign molecules is also decreased. Glucocorticoids decrease interleukin-1

production, blocking cell-mediated immunity and reducing the patient's ability to fight infections. Other side effects include ulcers, hypertension, diabetes mellitus, and atherosclerosis.

Abnormally large amounts of glucocorticoids, whether due to disease or steroid medication, can result in **Cushing's syndrome**. In this condition, excess glucose is converted to fat and deposited about the trunk. Edema gives the patient's face a full-moon appearance. Blood glucose level may increase by as much as 50% above normal, causing *adrenal diabetes*. If this condition persists for several months, the beta cells in the pancreas may "burn out" from secreting excessive amounts of insulin, leading to permanent diabetes mellitus. Reduction

in protein synthesis causes weakness and decreased immune responses.

Many other hormones help regulate life processes

Many other tissues of the body secrete hormones. The **pineal gland**, located in the brain, produces **melatonin**, which is derived from the amino acid tryptophan. Melatonin influences biological rhythms and the onset of sexual maturity. In humans, melatonin facilitates the onset of sleep. Interestingly, exposure to light suppresses melatonin secretion.

As we have discussed, several hormones secreted by the digestive tract and by adipose tissue regulate digestive processes (see Chapter 47). The **thymus gland** produces **thymosin**, a hormone that plays a role in immune responses. **Atrial natriuretic peptide**, secreted by the atrium of the heart, promotes sodium excretion and lowers blood pressure (see Chapter 48). We discuss reproductive hormones in Chapter 50.

CHECKPOINT 49.5

- **CONNECT** Why is the hypothalamus considered the link between the nervous and endocrine systems? What is the role of the anterior pituitary gland? of the posterior pituitary?
- **VISUALIZE** Draw a diagram illustrating how thyroid hormone secretion is regulated.
- **PREDICT** Imagine that you eat a hot fudge sundae. What would be the response of your pancreas? What are the antagonistic actions of insulin and glucagon in regulating blood glucose level?
- **PREDICT** Imagine that you are being chased by an alligator. How would your adrenal glands respond? How would that help? (Be specific.)
- How is regulation of the adrenal medulla different from regulation of the adrenal cortex?

Summary: Focus on Learning Objectives

49.1 An Overview of Endocrine Regulation

(page 1051)

- 1 Compare endocrine system function with nervous system function and describe how these systems work together to regulate body processes.
 - The **endocrine system** consists of endocrine glands, cells, and tissues that secrete **hormones**, chemical signals that regulate physiological processes. Most endocrine responses are slow but long-lasting. The endocrine system signals a wide range of **target cells**.
 - The nervous system responds rapidly to stimuli by transmitting electrical and chemical signals. Neurons signal other neurons, muscle cells, and gland cells, including endocrine cells. The nervous system helps regulate many endocrine responses.
- 2 Summarize the regulation of endocrine action by negative feedback systems.
 - Hormone secretion is typically regulated by **negative feedback systems**. A hormone is released in response to some change in a steady state. The hormone triggers a response that counteracts the changed condition. This process restores homeostasis.
- 3 Identify four main chemical groups to which hormones are assigned and give two examples for each group.
 - Prostaglandins and the juvenile hormone of insects are **fatty acid derivatives**. Hormones secreted by the adrenal cortex, ovary, and testis, as well as the molting hormone of insects, are **steroid hormones**.

- Thyroid hormones and epinephrine are **amino acid derivatives**. Antidiuretic hormone (ADH) and glucagon are examples of **peptide hormones**. Insulin is a small protein.

49.2 Types of Endocrine Signaling (page 1053)

- 4 Compare four types of endocrine signaling.
 - In *classical endocrine signaling*, discrete **endocrine glands**, glands without ducts, secrete hormones into the interstitial fluid. Hormones are transported by the blood. They bind with receptors on or in specific target cells.
 - In *neuroendocrine signaling*, neurons secrete **neurohormones**. These hormones are transported down axons and then secreted; they are typically transported by the blood.
 - In *autocrine signaling*, a hormone (or other signal molecule) is secreted into the interstitial fluid and then acts on the very cell that produced it.
 - In *paracrine signaling*, a hormone (or other signal molecule) diffuses through interstitial fluid and acts on nearby target cells.
 - Some **local regulators** are considered hormones; they use autocrine or paracrine signaling. Local regulators include **growth factors**, peptides that stimulate cell division and development, and **prostaglandins**, a group of local hormones that help regulate many metabolic processes.

49.3 Mechanisms of Hormone Action (page 1055)

- 5 Compare the mechanism of action of small, lipid-soluble hormones with that of hydrophilic hormones; include the role of second messengers, such as cyclic AMP.
- Steroid hormones and thyroid hormones are small, lipid-soluble molecules that pass through the plasma membrane and combine with receptors within the target cell; the hormone–receptor complex may activate or repress transcription of messenger RNA coding for specific proteins.
 - Peptide hormones are hydrophilic and do not enter target cells. They combine with receptors on the plasma membrane of target cells. Many hormones bind to **G protein-linked receptors** that act via **signal transduction**. An extracellular hormone signal is transduced into an intracellular signal by the receptor.
 - Most peptide hormones are first messengers that carry out their actions by way of **second messengers**, such as **cyclic AMP (cAMP)**. The G protein-linked receptor activates a **G protein**. The G protein either stimulates or inhibits an enzyme that affects the second messenger. For example, G proteins stimulate or inhibit **adenylyl cyclase**, the enzyme that catalyzes the conversion of ATP to cAMP.
 - Many second messengers stimulate the activity of *protein kinases*, enzymes that phosphorylate specific proteins that affect some cell process.
 - Some G proteins use phospholipid derivatives as second messengers. *Inositol trisphosphate (IP₃)* and *diacylglycerol (DAG)* are second messengers that increase calcium concentration and activate enzymes. Calcium ions bind with *calmodulin*, which activates certain enzymes.
 - **Tyrosine kinase receptors** are **enzyme-linked receptors** that bind growth factors, including insulin and nerve growth factor.

49.4 Neuroendocrine Regulation in Invertebrates (page 1058)

- 6 Identify four functions of invertebrate neurohormones and describe the regulation of insect development.
- Invertebrate hormones and neurohormones help regulate metabolism, growth and development, regeneration, color changes, molting, metamorphosis, reproduction, and behavior.
 - Hormones control development in insects. When stimulated by some environmental factor, neuroendocrine cells in the insect brain secrete *brain hormone (BH)*. BH stimulates the prothoracic glands to produce *molting hormone (MH)*, which stimulates growth and molting.
 - In the immature insect, the *corpora allata* secrete *juvenile hormone (JH)*, which suppresses metamorphosis at each larval molt. The amount of JH decreases with successive molts.

49.5 Endocrine Regulation in Vertebrates (page 1058)

- 7 Identify the classical vertebrate endocrine glands and describe the actions of their hormones; describe the effects of hypersecretion and hyposecretion on homeostasis.
- Consult Table 49-1 for a description of the main endocrine glands and their actions. Vertebrate hormones regulate growth and development, reproduction, salt and fluid balance, and many aspects of metabolism and behavior.
 - **Hyposecretion** (abnormally reduced output) or **hypersecretion** (abnormally increased output) of hormones leads to disruption of homeostasis and specific endocrine disorders.

- 8 Describe the mechanisms by which the hypothalamus and pituitary gland integrate regulatory functions; summarize the actions of the hypothalamic and pituitary hormones.

- Nervous and endocrine regulation is integrated in the **hypothalamus**, which regulates the activity of the **pituitary gland**.
- The neurohormones **oxytocin** and **antidiuretic hormone (ADH)** are produced by the hypothalamus and released by the **posterior pituitary** of the pituitary gland. Oxytocin stimulates contraction of the uterus and stimulates ejection of milk by the mammary glands. ADH stimulates reabsorption of water by the kidney tubules.
- The hypothalamus secretes **releasing hormones** and **inhibiting hormones** that regulate the hormone output of the **anterior pituitary gland**.
- The anterior pituitary secretes prolactin, melanocyte-stimulating hormones, growth hormone, and several **tropic hormones** that stimulate other endocrine glands. **Melanocyte-stimulating hormones (MSH)** suppress appetite and are important in regulating energy and body weight. **Prolactin** stimulates the mammary glands to produce milk.
- **Growth hormone (GH)** is an **anabolic hormone** that stimulates body growth by promoting protein synthesis. GH stimulates the liver to produce **insulin-like growth factors (IGFs)**, which promote skeletal growth and general tissue growth.

- 9 Describe the actions of the thyroid and parathyroid hormones, their regulation, and the effects of malfunction.

- The **thyroid gland** secretes thyroid hormones: **thyroxine**, or **T₄**, and **triiodothyronine**, or **T₃**. Thyroid hormones stimulate the rate of metabolism.
- Regulation of thyroid secretion depends mainly on a negative feedback system between the anterior pituitary gland and the thyroid gland.
- Hyposecretion of thyroxine during childhood may lead to **cretinism**; during adulthood it may result in **myxedema**. **Goiter**, an abnormal enlargement of the thyroid gland, is associated with both hyposecretion and hypersecretion. The most common cause of hyperthyroidism is **Graves' disease**, an autoimmune disease.
- The **parathyroid glands** secrete **parathyroid hormone (PTH)**, which regulates the calcium level in the blood. PTH increases calcium concentration by stimulating calcium release from bones, increasing calcium reabsorption by kidney tubules, and increasing calcium reabsorption from the intestine.
- **Calcitonin**, secreted by the thyroid gland, acts antagonistically to parathyroid hormone.

- 10 Contrast the actions of insulin and glucagon, and describe diabetes mellitus and hypoglycemia, including the metabolic effects of these disorders.

- The **islets of Langerhans** in the pancreas secrete **insulin** and **glucagon**. Insulin and glucagon secretion is regulated directly by glucose concentration. Insulin stimulates cells to take up glucose from the blood, so it lowers blood glucose concentration. Glucagon raises blood glucose concentration by stimulating conversion of glycogen to glucose and by stimulating production of glucose from other nutrients.

- In **diabetes mellitus**, either insulin deficiency or **insulin resistance** results in decreased use of glucose, increased fat mobilization, increased protein use, and electrolyte imbalance. In *hypoglycemia*, impaired glucose tolerance results in a delayed insulin response followed by hypersecretion of insulin. The glucose concentration falls, causing drowsiness.

11 Describe the actions and regulation of the adrenal hormones, including their role in the body's response to stress.

- Each **adrenal gland** consists of an inner adrenal medulla and an outer adrenal cortex. The **adrenal medulla** secretes **epinephrine** and **norepinephrine**, hormones that help the body cope with stress. These hormones increase heart rate, metabolic rate, and strength of muscle

contraction. They reroute blood to organs needed for fight or flight. The adrenal medulla is regulated by the nervous system.

- The **adrenal cortex** secretes sex hormones; **mineralocorticoids**, such as **aldosterone**; and **glucocorticoids**, such as **cortisol**. Aldosterone increases the rate of sodium reabsorption and potassium excretion by the kidneys.
- During stress, the adrenal cortex ensures adequate fuel supplies for the rapidly metabolizing cells. Cortisol promotes glucose synthesis from other nutrients. During stress, the hypothalamus secretes **corticotropin-releasing factor (CRF)**, which stimulates the anterior pituitary gland to secrete **adrenocorticotrophic hormone (ACTH)**. ACTH regulates both aldosterone and cortisol secretion.

Test Your Understanding

Know and Comprehend

1. A cell secretes a product that diffuses through the interstitial fluid and acts on nearby cells. This process is an example of (a) neuroendocrine secretion (b) autocrine signaling (c) paracrine signaling (d) classical endocrine regulation (e) peptide hormone function
2. Which of the following is/are *true* of steroid hormones? (a) hydrophilic (b) secreted by the posterior pituitary (c) typically work through G proteins and cyclic AMP (d) typically bind with receptor in nucleus and affect transcription (e) a and c are correct
3. Which of the following is *not* a correct pair? (a) neuro-hormone; insect brain hormone (b) calcium; calmodulin (c) posterior pituitary; releasing hormone (d) anterior pituitary; growth hormone (e) thyroid hyposecretion; cretinism
4. Growth hormone (a) signals the hypothalamus to produce a releasing hormone (b) is regulated mainly by calcium level (c) is a catabolic hormone (d) stimulates metabolic rate (e) stimulates the liver to produce insulin-like growth factors
5. Which of the following occurs in diabetes mellitus? (a) decreased use of glucose (b) decreased fat metabolism (c) decreased protein use (d) increased concentration of TSH-releasing hormone (e) b and c are correct
6. Which of the following is an action of epinephrine? (a) decreases glucose use (b) increases cardiac output (c) constricts blood vessels in brain (d) reduces inflammation (e) mobilizes fat
7. Aldosterone (a) is released by posterior pituitary (b) is an androgen (c) secretion is stimulated by an increase in thyroid-stimulating hormone (d) is an enzyme that converts epinephrine to norepinephrine (e) increases sodium reabsorption

Apply and Analyze

8. Arrange the following events into an appropriate sequence. 1. high thyroid hormone concentration 2. anterior pituitary inhibited 3. homeostasis 4. lower level of thyroid-stimulating hormone 5. thyroid gland secretes less thyroid hormone (a) 1, 2, 4, 5, 3 (b) 5, 4, 3, 2, 1 (c) 1, 2, 5, 4, 3 (d) 4, 5, 2, 3, 1 (e) 1, 4, 2, 5, 3

9. Arrange the following events into an appropriate sequence. 1. blood glucose concentration increases 2. alpha cells in islets stimulated 3. homeostasis 4. low blood glucose concentration 5. glucagon secretion increases (a) 1, 2, 3, 5, 4 (b) 5, 4, 2, 1, 3 (c) 1, 2, 5, 4, 3 (d) 4, 2, 5, 1, 3 (e) 4, 5, 1, 2, 3
10. **VISUALIZE** Draw a diagram illustrating the regulation of blood glucose concentration.
11. Why is it important to maintain a constant blood glucose level? Several hormones discussed in this chapter affect carbohydrate metabolism. Why is it important to have more than one? How do they interact?
12. An injection of too much insulin may cause a diabetic to go into insulin shock, in which the person may appear drunk or may become unconscious, suffer convulsions, and even die. From what you know about the actions of insulin, explain the physiological causes of insulin shock.

Evaluate and Synthesize

13. How do receptors impart specificity within the endocrine system? What might be some advantages of having complex mechanisms for hormone action (such as second messengers)?
14. **EVOLUTION LINK** The receptor for aldosterone appears to have evolved much earlier than aldosterone itself. Propose a hypothesis to explain how that might have occurred.
15. **SCIENCE, TECHNOLOGY, AND SOCIETY** The "thrifty gene" hypothesis holds that the genes that increase risk for type 2 diabetes allow efficient utilization of food (and fat accumulation) when food is available. In times of food scarcity, this efficiency increases chances of survival. Use this hypothesis to explain the rising rate of diabetes in the United States and suggest how science and technology may partner with society to reduce incidence of the disease.

For access to MindTap and additional study materials visit www.cengagebrain.com.

50 Reproduction

KEY CONCEPTS

- 50.1** Most animals reproduce sexually by fusion of sperm and egg; some animals reproduce asexually; and others can reproduce either way, depending on conditions.
- 50.2** In male vertebrates, testes produce sperm and reproductive hormones. In humans and other mammals, reproduction is regulated by hormones produced by the hypothalamus, pituitary gland, and gonads.
- 50.3** In female vertebrates, ovaries produce ova and reproductive hormones. In human females, hormones maintain a monthly menstrual cycle that prepares the body for possible pregnancy.
- 50.4** When a secondary oocyte is fertilized, development begins, and the embryo implants in the wall of the uterus; hormones from the developing embryo, from the corpus luteum, and later from the placenta maintain the pregnancy.
- 50.5** In both human males and females, sexual response includes four physiological stages: excitement phase, plateau phase, orgasmic phase, and resolution phase.
- 50.6** A variety of highly reliable contraceptives are available; most hormonal contraceptives prevent ovulation.
- 50.7** Sexually transmitted infections (STIs) are communicable diseases; the most common STIs in the United States include chlamydia (which can lead to pelvic inflammatory disease), human papillomavirus (HPV), and genital herpes.

The survival of each species requires that its members produce new individuals to replace those that die. The ability to reproduce and perpetuate its species is a basic characteristic of living things. To paraphrase U.S. sociobiologist E.O. Wilson, animal reproduction is an animal's way of making more copies of its genes. How this process is accomplished depends on the relative benefits (and costs) of the reproductive strategies available in any given situation.

The mating nudibranchs (marine slugs) in the photograph are *hermaphrodites*. Each animal has both male and female organs and produces both sperm and eggs. However, they do not self-fertilize. Two nudibranchs come together to mate and exchange sperm through a tube near the head. Each then goes its own way and lays masses containing millions of eggs.

In this chapter we summarize some major features of animal reproduction and discuss the evolutionary advantages of sexual reproduction. We then focus on the process of human reproduction and on the hormones that regulate reproduction. We limit our discussion to a binary (that is, female/male) consideration of the sexes. As you read, remember that sex and gender in humans have many aspects that are the focus of ongoing scientific research. Among these aspects are genetic and chromosomal factors (see Chapters 11 and 16), developmental processes (see Chapter 51 and Fig. 51-16), gender identification, and sexual orientation. We conclude the chapter with discussions of contraception and sexually transmitted infections.

50.1 Asexual and Sexual Reproduction

LEARNING OBJECTIVE

- 1 Compare the benefits of asexual and sexual reproduction, and describe each mode of reproduction, giving specific examples.

Most animals carry on *sexual reproduction*, and some carry on *asexual reproduction*. Some animals reproduce asexually under some conditions and sexually at other times. As we will discuss, many variations of both asexual and sexual reproduction have evolved.

Asexual reproduction is an efficient strategy

In **asexual reproduction**, a single parent gives rise to offspring that are genetically identical to the parent (with the exception of mutations). Many invertebrates, including sponges, cnidarians, and some rotifers, flatworms, and annelids, can reproduce asexually. Some vertebrates also reproduce asexually under certain conditions. Asexual reproduction is an adaptation of some sessile animals that cannot move about to search for mates. For animals that do move about, asexual reproduction can be advantageous when the population density is low and mates are not readily available.

In asexual reproduction, a single parent may split, bud, or fragment to give rise to two or more offspring. Sponges and cnidarians are among the animals that can reproduce by **budding**. A small part of the parent's body separates from the rest and develops into a new individual (FIG. 50-1). Sometimes the buds remain attached and become more or less independent members of a colony.

Oyster farmers learned long ago that when they tried to kill sea stars by chopping them in half and throwing the pieces back into the sea, the number of sea stars preying on the oyster bed doubled! In some flatworms, nemerteans, and annelids, this ability to regenerate is part of a method of reproduction known as **fragmentation**. The body of the parent breaks into several pieces; each piece then regenerates the missing parts and develops into a whole animal.

Parthenogenesis ("virgin development") is a form of asexual reproduction in which an unfertilized egg develops into an adult animal. The adult is typically haploid. Parthenogenesis is common among insects (especially honeybees and wasps) and crustaceans; it also occurs among some other invertebrate and vertebrate groups, including some species of nematodes, gastropods, fishes, amphibians, and reptiles.

Although a few species appear to reproduce solely by parthenogenesis, in most species episodes of parthenogenesis alternate with periods of sexual reproduction. Parthenogenesis may occur for several generations, followed at some point by sexual reproduction in which males develop, produce sperm, and mate with the females to fertilize their eggs. In some species, parthenogenesis is a means of rapidly producing individuals when conditions are favorable.

Figure 50-1 Asexual reproduction by budding

A part of the *Hydra*'s body grows outward (right), then it separates and develops into a new individual. The region of the parent body that buds is not specialized exclusively for reproduction. The *Hydra* shown here is also reproducing sexually, as evidenced by the egg (left).

Most animals reproduce sexually

Sexual reproduction in animals involves the production and fusion of two types of **gametes**: sperm and eggs. Typically, two different individuals are required. A male parent contributes a **sperm**, and a female parent contributes an egg, or **ovum** (pl., *ova*). The sperm provides genes coding for some of the male parent's traits, and the egg contributes genes coding for some of the female parent's traits. The egg is typically large and non-motile, with a store of nutrients that supports the development of the embryo. The sperm is usually small and motile, and is adapted to propel itself by beating its long, whiplike flagellum.

When sperm and egg unite, a **zygote**, or fertilized egg, is produced. The zygote develops into a new animal, similar to both parents but not identical to either. Sexual reproduction typically involves remarkably complex structural, functional, and behavioral processes. In vertebrates, hormones secreted by the hypothalamus, pituitary gland, and gonads regulate these processes.

Many aquatic animals practice **external fertilization** in which the gametes meet outside the body (FIG. 50-2a). Mating partners usually release eggs and sperm into the water simultaneously. Gametes live for only a short time, and many are lost in the water; some are eaten by predators. However, so many gametes are released that sufficient numbers of sperm and egg cells meet to perpetuate the species.

In **internal fertilization**, matters are left less to chance. The male generally delivers sperm cells directly into the body of the female. Her moist tissues provide the watery medium required

for the movement of sperm, and the gametes fuse inside the body. Most terrestrial animals, sharks, and aquatic reptiles, birds, and mammals practice internal fertilization (FIG. 50-2b).

Hermaphroditism is a form of sexual reproduction in which a single individual produces both eggs and sperm. A few hermaphrodites, such as the tapeworm, are capable of self-fertilization. More typically, two animals come together and fertilize each other's eggs (see the chapter-opening photograph of mating nudibranchs). The common earthworm is also a hermaphrodite. Two animals copulate, and mutual cross-fertilization occurs. Each earthworm inseminates the other. In some hermaphroditic species, self-fertilization is prevented by the development of testes and ovaries at different times.

Sexual reproduction increases genetic variability

Asexual reproduction is the fastest and most efficient way to reproduce. Each cell can produce two new cells. Sexual reproduction is less efficient than asexual reproduction because two cells, rather than just one, are required to make a new organism. (Two parents are typically required.) Sexual reproduction is also more expensive in terms of energy than asexual reproduction because the animal must produce gametes and find mates. If asexual reproduction has so many advantages, you may wonder why most animals reproduce sexually.

A major benefit of sexual reproduction is that it has the potential to increase the *fitness* (reproductive success) of some of the offspring. In contrast to asexual reproduction, in which an animal passes all its genes to its offspring, sexual reproduction has the biological advantage of promoting genetic variety among the members of a species. Each offspring is the product of a particular combination of genes contributed by both parents rather than a genetic copy of a single individual. By combining inherited traits of two parents, sexual

reproduction gives rise to at least some offspring that may be better able to survive than either parent. Also, because the offspring are diploid, they have a backup copy of their genes in case one copy gets damaged by mutation.

Although they agree that sexual reproduction has some selective advantage, biologists do not agree on the details. They are exploring several hypotheses. One hypothesis holds that sexual reproduction provides a mechanism for beneficial mutations from each parent to come together in offspring that can reproduce and spread these mutations through the population. For example, certain beneficial mutations may permit animals to protect themselves from predators or resist parasites.

Another hypothesis holds that sexual reproduction is more efficient than asexual reproduction at removing harmful mutations from a population. As you have learned in earlier chapters, mutations occur constantly, and most mutations are harmful. When animals reproduce asexually, all the offspring inherit all the harmful mutations. As mutations accumulate in a population, individuals carry a bigger and bigger load of harmful genes. In contrast, when animals with different mutations mate, offspring inherit varying numbers and combinations of mutations. Offspring that inherit too many harmful mutations are selected against. They may not live to reproduce, so their harmful mutations are removed from the population.

(a) External fertilization. Like many aquatic animals, these spawning frogs (*Rana temporaria*) release their gametes into the water. The female lays a mass of eggs, while the male mounts her and simultaneously deposits his sperm in the water.

(b) Internal fertilization. In most terrestrial animals, such as these lions (*Panthera leo*), the male deposits sperm inside the female body. Internal fertilization is also practiced by some fishes and some aquatic reptiles and mammals.

Figure 50-2 Sexual reproduction: external and internal fertilization

Wayne Getz, an applied mathematician at the University of California, Berkeley, developed a mathematical model that predicts whether asexual reproduction or sexual reproduction will exist within a population. According to his model, clones of animals produced by asexual reproduction would be favored in an unchanging environment. The model further predicts that sexual reproduction will be adaptive in an unstable, changing environment and that both types of reproduction can coexist under conditions of moderate change.

Competing hypotheses are an expected part of the scientific process because scientific discovery is rarely a straightforward, linear sequence of question–answer, question–answer. In fact, as scientific knowledge expands, many creative hypotheses are falsified or discarded as dead ends. Sometimes researchers show that competing hypotheses may each explain part of the problem under scrutiny.

CHECKPOINT 50.1

- Distinguish among budding, fragmentation, and parthenogenesis.
- What are the advantages and disadvantages of asexual reproduction compared with sexual reproduction?

50.2 Human Reproduction: The Male

LEARNING OBJECTIVES

- 2 Relate the structure of each organ of the human male reproductive system to its function.
- 3 Trace the passage of sperm cells through the human male reproductive system from their origin in the seminiferous

(a) **Male reproductive anatomy.** The scrotum, penis, and pelvic region of the human male are shown in sagittal section to illustrate their internal structure.

Figure 50-3 Male reproductive system

tubules to their expulsion from the body in the semen; include a description of spermatogenesis.

- 4 Describe endocrine regulation of reproduction in the human male.

The human male, like other male mammals, has the reproductive role of producing sperm cells and delivering them into the female reproductive tract. When a sperm combines with an egg, the sperm contributes its genes and determines the sex of the offspring.

The testes produce gametes and hormones

In humans and other vertebrates, **spermatogenesis**, the process of sperm cell production, occurs in the paired male gonads, or **testes** (sing., *testis*) (**FIG. 50-3a**). More specifically, spermatogenesis takes place within a vast tangle of hollow tubules, the **seminiferous tubules**, within each testis (**FIG. 50-3b**). Spermatogenesis begins with undifferentiated cells, the **spermatogonia** (sing., *spermatogonium*) in the walls of the tubules (**FIG. 50-4**).

The spermatogonia, which are diploid cells, divide by mitosis and produce more spermatogonia. Some enlarge and become **primary spermatocytes**, which undergo **meiosis**. (You may want to review the discussion of meiosis in Chapter 10.) In many animals, gamete production occurs only in the spring or fall, but humans have no special breeding season. In the human adult male, spermatogenesis proceeds continuously, and millions of sperm are produced each day.

(b) **Structures that produce and transport sperm.** The testis, epididymis, and spermatic cord are shown partly dissected and exposed. The testis is shown in sagittal section to illustrate the arrangement of the seminiferous tubules.

Figure 50-4
Spermatogenesis in the seminiferous tubules

(a) Color-enhanced SEM of a cross section through a seminiferous tubule. Flagella (blue) of maturing sperm are visible in the center. Developing sperm are nourished by large Sertoli cells (both green). A connective tissue sheath (gray) surrounds each tubule.

(b) Sperm cells in various stages of development. Developing sperm cells lie among the large, nutritive Sertoli cells.

Each primary spermatocyte undergoes a first meiotic division, which produces two haploid **secondary spermatocytes** (FIG. 50-5). During the second meiotic division, each of the two secondary spermatocytes gives rise to two haploid **spermatids**. Four spermatids are produced from the original primary spermatocyte. Each spermatid differentiates into a mature sperm. The sequence is as follows:

spermatogonium (diploid) → primary spermatocyte (diploid) → two secondary spermatocytes (haploid) → four spermatids (haploid) → four mature sperm (haploid)

Each mature sperm consists of a head, midpiece, and flagellum (FIG. 50-6). The head consists almost entirely of the nucleus. Part of the nucleus is covered by the **acrosome**, a large vesicle that differentiates from the Golgi complex. The acrosome contains enzymes that help the sperm penetrate the egg.

Mitochondria, located in the midpiece of the sperm, provide the energy for movement of the flagellum. The sperm flagellum has the typical eukaryotic 9 + 2 arrangement of microtubules. During its development, most of the sperm's cytoplasm is discarded and is phagocytosed by the large **Sertoli cells** that ring the fluid-filled lumen of the seminiferous tubule. These cells provide nutrients for the developing sperm cells. Sertoli cells also secrete hormones and other signaling molecules.

Each Sertoli cell extends from the outer membrane of the seminiferous tubule to its lumen. Sertoli cells are joined to one another by **tight junctions** at a place just within the outer membrane of the tubule (see Chapter 5 for discussion of tight junctions). Together, Sertoli cells form a blood–testis barrier that prevents harmful substances from entering the tubule and interfering with spermatogenesis. This barrier also prevents sperm from passing out of the tubule into the blood, where they could stimulate an immune response. The tight junctions between Sertoli cells also form compartments that separate sperm cells in various stages of development.

Human sperm cells cannot develop at body temperature. Although the testes develop within the abdominal cavity of the male embryo, about two months before birth they descend into the **scrotum**, a skin-covered sac suspended from the groin. The scrotum serves as a cooling unit, maintaining sperm below body temperature. In rare cases, the testes do not descend. If this condition is not corrected by surgery or hormone treatment, the seminiferous tubules eventually degenerate and the male becomes **sterile**, unable to produce offspring.

The scrotum is an outpocketing of the pelvic cavity and is connected to it by the **inguinal canals**. As they descend, the testes pull their blood vessels, nerves, and conducting tubes after them. The inguinal region is a weak place in the abdominal wall. Straining the abdominal muscles by lifting heavy objects sometimes tears the inguinal tissue. A loop of intestine can then bulge into the scrotum through the tear, a condition known as an **inguinal hernia**.

Figure 50-5 Spermatogenesis

Note in this example that four chromosomes are present in the primary spermatocyte ($2n$) and that meiosis produces the haploid (n) number (2) in the secondary spermatocytes. The spermatids and mature sperm cells are also haploid.

A series of ducts store and transport sperm

Sperm cells leave the seminiferous tubules of each testis and pass into a larger coiled tube, the **epididymis**. There, sperm finish

(a) A mature sperm has a head, midpiece, and flagellum. The acrosome contains enzymes important in penetrating the egg.

(b) Color-enhanced TEM of a human sperm cell.

Figure 50-6 Structure of a mature sperm

maturing and are stored. During **ejaculation**, sperm pass from each epididymis into a sperm duct, the **vas deferens** (pl., *vasa deferentia*). The vas deferens extends from the scrotum through the inguinal canal and into the pelvic cavity.

Each vas deferens empties into a short **ejaculatory duct**, which passes through the prostate gland and then opens into the single **urethra**. The urethra, which at different times conducts urine and semen, passes through the penis to the outside of the body. Thus, the sperm pass through the following structures:

seminiferous tubules → epididymis → vas deferens → ejaculatory duct → urethra → release from body

The accessory glands produce the fluid portion of semen

As sperm travel through the conducting tubes, they mix with secretions from three types of accessory glands. **Semen** consists

of about 200 million sperm cells suspended in these secretions. Approximately 3 mL of semen is ejaculated during sexual climax.

The paired **seminal vesicles** secrete a fluid rich in fructose and prostaglandins into the vasa deferentia (see Fig. 50-3). The fructose provides energy for the sperm after they are ejaculated. Prostaglandins stimulate contractions of smooth muscle in both male and female reproductive tracts. These contractions help transport the sperm down the male reproductive tract and up the female tract to the oviduct where fertilization occurs. The seminal vesicles also secrete fibrinogen, which clots the semen. The fluid secreted by the seminal vesicles accounts for about 60% of the semen volume.

The single **prostate gland** secretes an alkaline fluid that neutralizes the acidic secretions of the vagina. This process is important because sperm are more active and survive longer in a slightly alkaline environment. Prostate gland secretion also contains clotting enzymes and *prostate-specific antigen (PSA)*. The clotting enzymes act on fibrinogen from the seminal vesicles, producing fibrin. You may recall from Chapter 44 that fibrin threads form blood clots. In this case, fibrin clots the semen. When semen is ejaculated, the clotted semen helps keep the sperm in the female reproductive tract while the penis is withdrawn. The clot is then broken down by PSA, and mobile sperm make their way through the female reproductive tract to the ovum.

Except for skin cancer, prostate cancer is the most common cancer in males and is also one of the leading causes of cancer death among males in the United States. According to national guidelines, doctors should talk to their patients about the benefits and risks of PSA-based screening for prostate cancer for men without symptoms. Screening tests for prostate cancer include the digital rectal exam and the prostate specific antigen blood test (PSA). The PSA measures the concentration of PSA in the blood. Elevated concentrations of PSA are associated with prostate cancer, prostate infection, and certain benign changes in the prostate. An elevated PSA indicates a need for further evaluation, typically a prostate biopsy. Prostate cancer can be treated with surgery, hormone therapy, or radiation treatment.

During sexual arousal, the paired *bulbourethral glands*, located on each side of the urethra, release a mucous secretion. This fluid lubricates the penis, facilitating its penetration into the vagina.

A major cause of male infertility is insufficient sperm production. When sperm counts drop below 35 million per milliliter of semen, fertility is impaired, and males with a sperm count lower than 20 million per milliliter are usually considered sterile. When a couple's attempts to produce a child are unsuccessful, a sperm count and analysis may be performed in a clinical laboratory. Sometimes semen is found to contain large numbers of abnormal sperm or, occasionally, no sperm at all.

In the United States in the 1970s, an average healthy young man produced about 100 million sperm per milliliter of semen. Today that average has dropped to about 60 million. Although the cause of this decrease is not known, low sperm counts have been linked to a variety of environmental factors, including chronic marijuana use, alcohol abuse, and cigarette smoking. Studies also show that men who smoke tobacco are more likely than nonsmokers to produce abnormal sperm. Exposure to industrial and environmental toxins such as PCBs (polychlorinated

biphenyls) may contribute to low sperm count and sterility. The use of anabolic steroids by athletes to accelerate muscle development can cause sterility in both males and females (see *Inquiring About: Anabolic Steroids and Other Performance-Enhancing Drugs* in Chapter 49). A recent study identified two potentially modifiable factors that might lead to an increase in sperm count: increased exercise and decreased television viewing.

The penis transfers sperm to the female

The **penis** is an erectile copulatory organ that delivers sperm into the female reproductive tract. It is a long shaft that enlarges to form an expanded tip, the *glans*. Part of the loose-fitting skin of the penis folds down and covers the proximal portion of the glans, forming a cuff called the *prepuce*, or *foreskin*. The foreskin is removed during circumcision, a procedure commonly performed on male babies either for hygienic or religious reasons. Studies have documented that male circumcision significantly reduces a man's risk of acquiring **human immunodeficiency virus (HIV)** and other sexually transmitted infections during vaginal sexual intercourse.

Under the skin, the penis consists of three parallel columns of *erectile tissue*: two *cavernous bodies* and one *spongy body* (FIG. 50-7). The spongy body surrounds the portion of the urethra that passes through the penis. Erectile tissue contains numerous blood vessels. When the male is sexually stimulated, parasympathetic neurons dilate the arteries in the penis. As

Figure 50-7 Internal structure of the penis

blood fills the blood vessels of the erectile tissue, the tissue swells. This swelling compresses veins that conduct blood away from the penis, slowing the outflow of blood. Thus, more blood enters the penis than can leave, further engorging the erectile tissue with blood. Erection of the penis occurs as the penis increases in length, diameter, and firmness. Although the human penis contains no bone, penis bones do occur in some other mammals, such as bats, rodents, and some primates.

Erectile dysfunction, the chronic inability to sustain an erection, prevents effective sexual intercourse. Associated with a variety of physical causes and psychological issues, this common disorder is treated with medication, such as sildenafil (Viagra) and related drugs (Levitra, Cialis). These drugs block the action of an enzyme that breaks down the signaling molecule that sustains erection.

Testosterone has multiple effects

Testosterone is the principal **androgen**, or male sex hormone. It is a steroid produced by the **interstitial cells** between the seminiferous tubules in the testes. Testosterone has many functions, beginning during early embryonic development when it stimulates development of the primary male reproductive organs (TABLE 50-1). Later during development, testosterone stimulates descent of the testes into the scrotum.

Puberty is the period of sexual maturation during which the secondary sex characteristics begin to develop and the individual becomes capable of reproducing. In males, puberty typically begins between ages 10 and 12 and continues until ages 16 to 18. Testosterone directly affects muscle and bone and stimulates the adolescent growth spurt in males at puberty. It produces the male's *primary sex characteristics*: growth of the reproductive organs and spermatogenesis. Testosterone also stimulates the development of the **secondary sex characteristics** at puberty, including growth of facial and body hair, muscle development, and the increase in vocal cord length and thickness that causes the voice to deepen. Testosterone is necessary for normal sex drive.

In some of its target tissues, testosterone is converted to other steroids. Interestingly, in brain cells testosterone is converted to *estradiol*, the principal female sex hormone. The implications of this transformation are not yet understood.

The hypothalamus, pituitary gland, and testes regulate male reproduction

As you read the following description of male hormone action and regulation, follow the steps in **FIGURE 50-8**. When a boy is about 10 years old, the hypothalamus begins to secrete **gonadotropin-releasing hormone (GnRH)**. GnRH stimulates the anterior pituitary to secrete the *gonadotropic hormones* **follicle-stimulating hormone (FSH)** and **luteinizing hormone (LH)**. Both FSH and LH are glycoproteins that use cyclic AMP as a second messenger (see Chapter 49). FSH stimulates Sertoli cells to secrete **androgen-binding protein (ABP)** and other signaling molecules that are necessary for spermatogenesis. LH stimulates the interstitial cells to secrete testosterone.

FSH, LH, and testosterone all directly or indirectly stimulate testosterone secretion and spermatogenesis. A high concentration of testosterone in the testes is required for spermatogenesis. Testosterone and FSH stimulate Sertoli cells to produce ABP, which binds to testosterone and concentrates it in the tubules. Testosterone also maintains the male secondary sex characteristics.

Reproductive hormone concentrations are regulated by negative feedback mechanisms (see Fig. 50-8b). Testosterone acts on the hypothalamus, decreasing its secretion of GnRH, which decreases FSH and LH secretion by the pituitary. Testosterone also directly inhibits the anterior lobe of the pituitary by blocking the normal actions of GnRH on LH synthesis and release.

FSH secretion is inhibited mainly by **inhibin**, a peptide hormone secreted by Sertoli cells. FSH itself stimulates inhibin secretion. The endocrine regulation of reproductive function is complex, and it is likely that other hormones and signaling molecules will be identified.

Table 50-1 Principal Male Reproductive Hormones		
Endocrine Gland and Hormones	Principal Target Tissue	Principal Action
HYPOTHALAMUS		
Gonadotropin-releasing hormone (GnRH)	Anterior pituitary	Stimulates release of FSH and LH
ANTERIOR PITUITARY		
Follicle-stimulating hormone (FSH)	Testes	Stimulates development of seminiferous tubules; stimulates spermatogenesis
Luteinizing hormone (LH)	Testes	Stimulates interstitial cells to secrete testosterone
TESTES		
Testosterone	General	Before birth: stimulates development of primary sex organs and descent of testes into scrotum At puberty: responsible for growth spurt; stimulates development of reproductive structures and secondary sex characteristics In adult: maintains secondary sex characteristics; stimulates spermatogenesis
Inhibin	Anterior pituitary	Inhibits FSH secretion

Key Point

Hormones from the hypothalamus, anterior pituitary gland, and testes regulate male reproduction by negative feedback systems.

Insufficient testosterone results in sterility. If a male is *castrated*—that is, the testes are removed—before puberty, he is deprived of testosterone and becomes a eunuch. He retains childlike sexual organs and does not develop secondary sexual characteristics. If castration occurs after puberty, increased secretion of male hormones by the adrenal glands helps maintain masculinity.

CHECKPOINT 50.2

- What are the functions of the testes?
- VISUALIZE** Draw a diagram showing the structures through which a sperm passes in its journey from a seminiferous tubule until it leaves the male body during ejaculation.
- What are the actions of testosterone?
- VISUALIZE** Draw and label a diagram illustrating the endocrine regulation of male reproduction. (Include LH, FSH, GnRH, ABP, testosterone, and inhibin.)

50.3 Human Reproduction: The Female

LEARNING OBJECTIVES

- Relate the structure of each organ of the human female reproductive system to its function.
- Trace the development of a human egg and trace its passage through the female reproductive system until it is fertilized.
- Describe the endocrine regulation of reproduction in the human female and identify key events of the menstrual cycle, such as ovulation and menstruation.

The female reproductive system produces ova (gametes), receives the penis and sperm released from it during heterosexual intercourse, houses and nourishes the embryo during prenatal development, gives birth, and produces milk for the young (lactation). Hormones secreted by the hypothalamus, pituitary gland, and ovaries interact to regulate and coordinate these processes.

The ovaries produce gametes and sex hormones

Like the male gonads, the female gonads, or **ovaries**, produce both gametes and sex hormones. About the size and shape of large almonds, the ovaries lie close to the lateral walls of the pelvic cavity and are held in position by several connective tissue ligaments (FIG. 50-9). Internally, the ovary consists mainly of connective tissue containing scattered ova in various stages of maturation.

The process of ovum production, called **oogenesis**, begins in the ovaries. Before birth, hundreds of thousands of **oogonia** are present in the ovaries. For more than 50 years, biologists agreed that all a female's oogonia were produced during embryonic development and that no new oogonia were produced after birth. Recently, a research team challenged this view, claiming that stem cells in the ovaries of women (and mice) continue to differentiate into ova throughout adulthood, until menopause.

During prenatal development, the oogonia increase in size and become **primary oocytes**. By the time of birth, they are in the prophase of the first meiotic division. At this stage, they enter a resting phase that lasts throughout childhood and into adult life.

A primary oocyte and the **granulosa cells** surrounding it together make up a **follicle** (FIG. 50-10). The granulosa cells are connected by tight junctions that form a protective barrier around the oocyte. With the onset of puberty, a few follicles begin to mature each month in response to FSH secreted by the anterior pituitary gland. As a follicle grows, the granulosa

cells proliferate, forming several layers. Connective tissue cells surrounding the granulosa cells differentiate to form a layer of **theca cells**.

As the follicle matures, the primary oocyte completes its first meiotic division. The two haploid cells produced differ in size (FIG. 50-11). The smaller one, the first **polar body**, may later divide, forming two polar bodies, but these cells eventually disintegrate. The larger cell, the **secondary oocyte**, proceeds to the second meiotic division but remains in metaphase II until it is fertilized. When meiosis continues, the second meiotic division gives rise to a single ovum and a second polar body. The polar bodies are small and apparently dispose of unneeded chromosomes with a minimal amount of cytoplasm. The sequence is as follows:

oogonium (diploid) → primary oocyte (diploid) → secondary oocyte + first polar body (both haploid) → (after fertilization) ovum + second polar body (both haploid)

Recall that in the male, each primary spermatocyte gives rise to four functional sperm cells. In contrast, each primary oocyte generates only one ovum.

As an oocyte develops, it becomes separated from its surrounding follicle cells by a layer of glycoproteins called the **zona pellucida**. As the follicle develops, follicle cells secrete fluid, which collects in the antrum (space) between them (see Fig. 50-10). The follicle cells also secrete **estrogens**, female sex hormones. The principal estrogen is *estradiol* (see Fig. 49-2b). Typically, only one follicle fully

(a) Midsagittal section through the female pelvis. Note the position of the uterus relative to the vagina.

(b) Anterior view of female reproductive system. Some organs have been cut open to expose their internal structure. Connective tissue ligaments anchor the reproductive organs in place.

Figure 50-9 Female reproductive system

matures each month. Several others may develop for a while and then deteriorate by apoptosis.

As a follicle matures, it moves closer to the surface of the ovary, eventually resembling a fluid-filled bulge on the ovarian surface. Follicle cells secrete proteolytic enzymes that break down a small area of the ovary wall. During **ovulation**, the secondary oocyte ejects through the ovary wall and into

the pelvic cavity. The portion of the follicle that remains in the ovary develops into the **corpus luteum**, a temporary endocrine gland that secretes estrogen and **progesterone**.

The oviducts transport the secondary oocyte

Almost immediately after ovulation, the secondary oocyte is swept into the funnel-shaped opening of the **oviduct**, also called the **uterine tube** or *fallopian tube*. Ciliated epithelial cells lining the oviduct sweep the secondary oocyte into the oviduct and move it along toward the uterus. Fertilization takes place within the oviduct. If fertilization does not occur, the secondary oocyte degenerates there.

Scarring of the oviducts (e.g., by *pelvic inflammatory disease*, caused by a sexually transmitted infection) can block the tubes so that the fertilized ovum cannot pass to the uterus. Women with blocked oviducts may be infertile. Sometimes partial constriction of the oviduct results in *tubal pregnancy*. The embryo cannot progress to the uterus, and it begins to develop in the wall of the oviduct. Because oviducts are not adapted to bear the burden of a developing embryo, the oviduct and the embryo it contains must be surgically removed before it ruptures and endangers the life of the mother.

The uterus incubates the embryo

The oviducts open into the upper corners of the pear-shaped **uterus** (see Fig. 50-9b). About the size of a fist, the uterus (or womb) occupies a central position in the pelvic cavity. It has thick walls of smooth muscle and an epithelial lining, the **endometrium**, which thickens each month in preparation

(a) LM of a developing follicle. The secondary oocyte is surrounded by the zona pellucida (a layer of glycoproteins) and by granulosa cells. Connective tissue cells surrounding the granulosa cells form a layer of theca cells.

(b) Follicles in the ovary. This drawing is a composite; all these stages of development would not be present at the same time.

Figure 50-10 Development of a follicle in the ovary

Figure 50-11 Oogenesis

Before birth, oogonia (*not shown*) divide many times by mitosis. Some oogonia differentiate to become primary oocytes that undergo meiosis. Only one functional ovum is produced from each primary oocyte. The other cells produced are polar bodies that degenerate. The first polar body sometimes divides as shown but often just deteriorates. The second meiotic division is completed after fertilization. Note in this example that four chromosomes are present in the primary oocyte ($2n$) and that meiosis produces the haploid (n) number (two chromosomes) in the polar bodies, secondary oocyte, and mature ovum.

for possible pregnancy. About 10% of women (more than ten million women in the United States alone) are affected by *endometriosis* during their reproductive years. In this painful disorder, fragments of the endometrium migrate to other areas, such as the oviducts or ovaries. Like pelvic inflammatory disease, endometriosis causes scarring that can lead to infertility.

If a secondary oocyte is fertilized, the tiny embryo enters the uterus and implants in the endometrium. As it grows and develops, it is sustained by nutrients and oxygen delivered by surrounding maternal blood vessels. If fertilization does not occur during the monthly cycle, the endometrium sloughs off and is discharged in the process known as **menstruation**.

The lower portion of the uterus, called the **cervix**, extends slightly into the vagina. Cervical cancer is the third most common type of cancer for females in the world. Almost all cases of cervical cancer are linked to infection with human papillomavirus (HPV). (Vaccines against HPV are described later in this chapter.) Detection of cervical cancer is usually possible by the routine Papanicolaou test (Pap smear), in which a few cells are scraped from the cervix during a regular gynecological examination and studied microscopically. When cervical cancer is detected at an early stage, there is a good chance that the patient can be cured. (Interestingly, researchers have reported that in the future, Pap smears may also be used to detect mutations that put women at high risk for developing ovarian cancer or uterine cancer.)

The vagina receives sperm

The **vagina** is an elastic, muscular tube that extends from the uterus to the exterior of the body. The vaginal opening is located in the *perineal region* between the opening of the urethra (anteriorly) and the opening of the anus (posteriorly). The vagina serves as a receptacle for sperm during heterosexual intercourse and as part of the birth canal (see Fig. 50-9).

The vulva are external genital structures

The female external genitalia, collectively known as the **vulva**, include several structures. Liplike folds, the *labia minora*, surround the vaginal and urethral openings (**FIG. 50-12**). The area enclosed by the labia minora is the *vestibule* of the vagina. Vestibular glands secrete a lubricating mucus into the vestibule. The *hymen* is a thin ring of tissue that forms a border around the entrance to the vagina.

Anteriorly, the labia minora merge to form the prepuce of the **clitoris**, a small erectile structure homologous to the male glans penis. Like the penis, the clitoris contains erectile tissue that becomes engorged with blood during sexual excitement. Rich in nerve endings, the clitoris is highly sensitive to touch, pressure, and temperature, and serves as the main center of sexual sensation in the female.

Figure 50-12 External female genital structures

Collectively, the structures shown (excluding the anus) are referred to as the vulva.

External to the delicate labia minora are the thicker *labia majora*. The *mons pubis* is the mound of fatty tissue just above the clitoris at the junction of the thighs and torso. At puberty the mons pubis and labia majora become covered by coarse pubic hair.

Breasts function in lactation

Each breast consists of 15 to 20 lobes of glandular tissue. The amount of adipose tissue around these lobes determines the size of the breasts and accounts for their softness. Gland cells are arranged in grapelike clusters called **alveoli** (FIG. 50-13). Ducts from each cluster join to form a single duct from each lobe, producing 15 to 20 tiny openings on the surface of each nipple. The breasts are the most common site of cancer in women, except for the skin (see *Inquiring About: Breast Cancer*).

Lactation is the production of milk for nourishing the young. During pregnancy, high concentrations of the female reproductive hormones, estrogen and progesterone, stimulate the breasts to increase in size. For the first few days after childbirth, the mammary glands produce a fluid called *colostrum*, which contains proteins and antibodies, but little fat. When the baby suckles, the hormone **prolactin**, secreted by the anterior pituitary gland, stimulates milk production. Nursing also stimulates the posterior pituitary gland to release **oxytocin**. This hormone stimulates ejection of milk from the alveoli into the ducts.

Breast-feeding promotes recovery of the uterus because oxytocin released during breast-feeding stimulates the uterus to contract to nonpregnant size. Breast-feeding offers advantages to the baby as well. It promotes bonding between mother and

child, and provides milk tailored to the nutritional needs of the human infant. Breast milk contains a variety of immune cells (B cells, T cells, neutrophils, and macrophages) and antibodies. As a result, breast-fed infants have a lower incidence of diarrhea, ear and respiratory infections, and hospital admissions than do formula-fed babies. According to the U.S. Surgeon General's Office, breast-fed babies also have a lower lifetime risk of asthma, obesity, type 2 diabetes, and other health problems.

The hypothalamus, pituitary gland, and ovaries regulate female reproduction

As in the male, regulation of female reproduction involves many hormones and other signaling molecules. In the male, concentration of sex hormones is kept within a narrow range. In contrast, concentrations of female sex hormones change dramatically during the course of each monthly cycle. **TABLE 50-2** lists the actions of the principal female reproductive hormones.

Like testosterone in the male, *estrogens* are responsible for growth of the sex organs at puberty, for body growth, and for the development of secondary sexual characteristics. In the female, these characteristics include development of the breasts, broadening of the pelvis, and the development and distribution of muscle and fat responsible for the female body shape. In females, *puberty* typically begins between ages 10 and 12 and continues until ages 14 to 16.

Figure 50-13 Structure of the mature female breast

The breast contains lobes of glandular tissue. This tissue consists of alveoli, clusters of gland cells.

Inquiring About

Breast Cancer

How common is breast cancer? According to the American Cancer Society, breast cancer is the most common type of cancer in the United States (exceeded only by skin cancer). More than 250,000 new cases of invasive breast cancer are diagnosed each year, and more than 40,000 women die from breast cancer every year. Breast cancer is the second leading cause of cancer deaths (exceeded only by lung cancer). Risk factors for breast cancer include being overweight (especially after menopause), alcohol use (more than two drinks per day), and lack of exercise. Some studies show that cigarette smoking is also a risk factor.

About 25 genetic mutations have been linked to breast and ovarian cancer. Women with a family history of breast cancer are at higher risk than those without such family history. An estimated 10% of breast cancers are familial, and about half of these patients have mutations in a tumor suppressor gene, either *BRCA1* or *BRCA2* (see Fig. 17-21). When the normal protein product of the *BRCA1* gene is phosphorylated by a specific protein kinase, it interacts with the normal protein product of the *BRCA2* gene and certain other compounds to repair DNA damage. Women with a family history of breast (or ovarian) cancer should seek genetic counseling and consider genetic testing. For those who test positive, there are now drugs available (such as tamoxifen) that decrease the risk of cancer. Some women choose preventive surgery.

About 50% of breast cancers begin in the upper, outer quadrant of the breast. As a malignant tumor grows, it may adhere to the deep tissue of the chest wall. Sometimes it extends to the skin, causing dimpling. Eventually, the cancer spreads to the lymphatic system. About two-thirds of breast cancers have metastasized (spread) to the lymph nodes by the time they are first diagnosed. When diagnosis and treatment begin early, about 86% of patients survive for five years, and 65% survive for 20 years or longer. Untreated patients have a 5-year survival rate of only 20%.

Common methods of treating breast cancer include mastectomy (surgical removal of the breast), chemotherapy, and radiation treatment.

Lumpectomy (surgical removal of only the affected portion of the breast) in conjunction with radiation treatment appears to be as effective as mastectomy in some cases. *Chemotherapy* (chemo) is treatment with drugs that kill cancer cells. Chemotherapy is often administered after surgery to destroy any cancer cells that may have broken away from the main tumor and escaped surgical removal. Even in the early stages of cancer, *metastasis* can occur: Cancer cells may move away from the primary tumor and establish new tumors in other parts of the body.

Targeted therapy involves the use of newer drugs that specifically target certain changes in

cancer cells. Targeted therapy is often used along with chemotherapy. For example, in about one in five individuals with breast cancer, HER2, a protein that promotes growth, is present in abnormally large amounts on the surface of cancer cells. Cancer cells with HER2 spread more aggressively than other cancer cells. Monoclonal antibodies, such as Herceptin, have been developed that slow the growth of these cells. These drugs may also stimulate the immune system to more effectively destroy the cancer.

To grow, tumors must stimulate growth of new blood vessels. A monoclonal antibody has been developed that targets the growth of new blood vessels that supply the tumors. New drugs are being developed that target specific proteins that promote tumor growth.

About two-thirds of breast cancers have estrogen or progesterone receptors. Growth of these cancers is enhanced by circulating estrogens and progesterone. Removing the ovaries in patients with these tumors relieves the symptoms and may cause remission of the disease for months or even years. Drugs (e.g., tamoxifen and aromatase inhibitors) have been developed that antagonize the action of estrogen receptors.

According to the American Cancer Society, when breast cancer is confined to the breast, the 5-year survival rate is almost 100%. Because early detection of breast cancer greatly increases the chances of cure and survival, self-examination and screening are important. The American Cancer Society recommends that women in their 20s and 30s should have a clinical breast exam by a health professional about every three years. After age 40, women should have an annual breast exam by a health professional. Women age 40 and older should have a screening mammogram annually. *Mammography*, a soft-tissue radiological study of the breast, is helpful in detecting very small lesions that might not be identified by routine examination. In mammography, lesions show on an X-ray plate as areas of increased density (see figure). Tomosynthesis, which is 3-D mammography, is increasing in use and appears to be a more effective way to image the breast, especially when it is dense.

Deco/Alamy Stock Photo

Mammogram showing area of breast cancer.

Cancer is seen as a dense mass (blue) in this colorized mammogram. The healthy fibrous tissue (lavender) supports the glandular structures.

Hormones of the hypothalamus, anterior pituitary, and ovaries regulate the **menstrual cycle**, the monthly sequence of events that prepares the body for possible pregnancy. (The term *menstrual cycle* is sometimes used more narrowly to refer to the changes that occur in the uterus; we use the term here to include both the ovarian and uterine cycles.) The menstrual cycle runs its course every month from puberty until *menopause*, which occurs at about age 50. Although wide variations exist, a typical menstrual cycle is 28 days long (FIG. 50-14).

The first two weeks of the menstrual cycle make up the *preovulatory phase*. Ovulation occurs on about the 14th day

of the cycle. The third and fourth weeks of the menstrual cycle are the *postovulatory phase*. As you read the following description of the menstrual cycle, follow the steps illustrated in FIGURE 50-15 on page 1090.

The preovulatory phase spans the first two weeks of the cycle

The first day of the menstrual cycle is marked by the onset of *menstruation*, the monthly discharge through the vagina of blood and tissue from the endometrium. Accordingly, the first five days or so of the preovulatory phase are known as the *menstrual phase*. During the first part of the preovulatory phase,

Table 50-2 Principal Female Reproductive Hormones

Endocrine Gland and Hormones	Principal Target Tissue	Principal Actions
HYPOTHALAMUS		
Gonadotropin-releasing hormone (GnRH)	Anterior pituitary	Stimulates release of FSH and LH
ANTERIOR PITUITARY		
Follicle-stimulating hormone (FSH)	Ovary	Stimulates development of follicles and secretion of estrogen
Luteinizing hormone (LH)	Ovary	Stimulates ovulation and development of corpus luteum
Prolactin	Breast	Stimulates milk production (after breast has been prepared by estrogen and progesterone)
POSTERIOR PITUITARY		
Oxytocin	Uterus Mammary glands	Stimulates contraction and stimulates prostaglandin release Stimulates ejection of milk into ducts
OVARIES		
Estrogens (estradiol)	General	Stimulates growth of sex organs at puberty and development of secondary sex characteristics
	Reproductive structures	Induces maturation; stimulates monthly preparation of endometrium for pregnancy; makes cervical mucus thinner and more alkaline
Progesterone	Uterus	Completes preparation of endometrium for pregnancy
Inhibin	Anterior pituitary	Inhibits secretion of FSH

the hypothalamus releases *gonadotropin-releasing hormone (GnRH)*. This hormone stimulates the anterior pituitary to release gonadotropic hormones: *follicle-stimulating hormone (FSH)* and *luteinizing hormone (LH)*. GnRH, FSH, and LH are the same hormones that help regulate reproduction in the male.

The preovulatory phase is also called the *follicular phase* because during this period, FSH stimulates a few follicles to begin to develop in the ovary. FSH also stimulates the granulosa cells of the follicle to multiply and produce estrogen. Some estrogen diffuses into the blood, but estrogen also has an *autocrine* action on the granulosa cells that produce it and a *paracrine* effect on nearby granulosa cells (see Chapter 49 for a discussion of autocrine and paracrine regulation). The amount of estrogen secreted by the granulosa cells is enhanced by the action of LH on the theca cells. LH stimulates the theca cells to proliferate and produce androgens. The androgens diffuse into the granulosa cells, where they are converted to estrogen. Estrogen stimulates growth of the endometrium, which begins to thicken and develop new blood vessels and glands.

Typically, after the first week of the menstrual cycle, only one follicle continues to develop. Its granulosa cells become sensitive to LH as well as to FSH. This dominant follicle now secretes enough estrogen to cause a rise in the concentration of estrogen in the blood. *Although still at relatively low concentration*, estrogen inhibits secretion of FSH from the pituitary. Estrogen also acts directly on certain neurons in the hypothalamus, which inhibit secretion of GnRH. In addition, the granulosa cells secrete *inhibin*, a hormone that mainly inhibits FSH secretion. As a result of these negative feedback signals, FSH concentration decreases.

As its concentration in the blood peaks during the late preovulatory phase, estrogen signals a different set of neurons in the hypothalamus to stimulate GnRH secretion. The GnRH stimulates the anterior pituitary to secrete LH, which

increases estrogen production by the follicle. This is a positive feedback mechanism. *The high estrogen concentration stimulates a surge in LH secretion.*

The surge of LH secreted at the middle of the menstrual cycle stimulates the final maturation of the follicle. The LH surge also stimulates *ovulation*, the ejection of the secondary oocyte from the ovary. The granulosa cells of the follicle decrease their estrogen output, resulting in a temporary decrease in estrogen concentration.

The corpus luteum develops during the postovulatory phase The postovulatory phase, also called the *luteal phase*, begins after ovulation. LH stimulates development of the corpus luteum, which secretes a large amount of progesterone and estrogen as well as inhibin. These hormones stimulate the uterus to continue its preparation for pregnancy. Progesterone stimulates tiny glands in the endometrium to secrete a fluid rich in nutrients.

During the postovulatory phase, the high concentration of progesterone in the blood, along with estrogen, inhibits secretion of GnRH, FSH, and LH. Progesterone acts on the hypothalamus and the anterior pituitary. Inhibin acts on the anterior pituitary to further inhibit FSH secretion. As a result of these negative feedback systems, FSH and LH concentrations are low during the postovulatory phase, and no new follicles develop.

If the secondary oocyte is not fertilized, the corpus luteum begins to degenerate after about eight days. Although the mechanism responsible for corpus luteum degeneration is not completely understood, the decrease in LH is an important factor. When the corpus luteum stops secreting progesterone and estrogen, the concentrations of these hormones in the blood fall markedly. As a result, small arteries in the endometrium constrict, reducing the oxygen supply. Menstruation,

Key Point

Gonadotropic hormones and ovarian hormones regulate the monthly sequence of events that take place within the ovary and uterus. The preovulatory phase begins with menstruation; the postovulatory phase begins after ovulation.

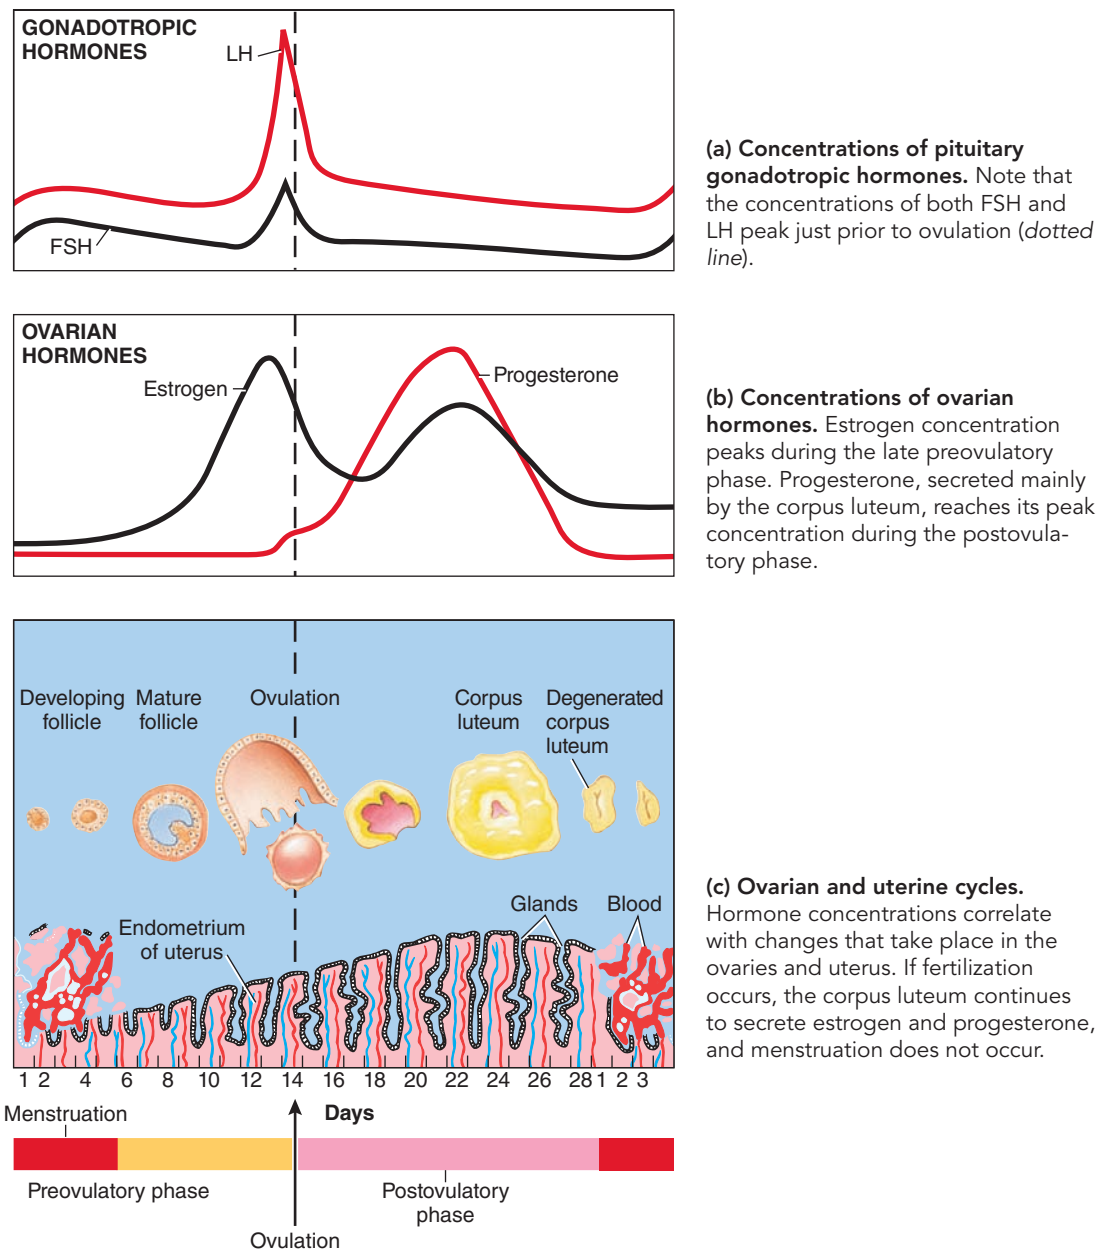

Figure 50-14 Endocrine regulation of the menstrual cycle

When fertilization does not occur, the menstrual cycle repeats about every 28 days. Note the changes in hormone concentrations that regulate the menstrual cycle. (FSH, follicle-stimulating hormone; LH, luteinizing hormone)

PREDICT What happens when a woman's ovaries produce a very low amount of estrogen?

which marks the beginning of a new cycle, begins as cells die and damaged blood vessels rupture and bleed. The concentrations of estrogen and progesterone are now too low to inhibit the anterior pituitary, and secretion of FSH and LH increases once again.

Menstrual cycles stop at menopause

At about age 50, a woman enters **menopause**, a period when ova are no longer produced and the woman becomes infertile. Apparently, a change in the hypothalamus triggers menopause.

Key Point

The hypothalamus, anterior pituitary, and ovary secrete hormones that regulate the menstrual cycle through feedback systems.

Figure 50-15 Feedback mechanisms in endocrine regulation of female reproduction

The secretion and interaction of hormones changes during the phases of the menstrual cycle. *Green arrows* indicate stimulation; *red arrows* indicate inhibition. (GnRH, gonadotropin-releasing hormone; FSH, follicle-stimulating hormone; LH, luteinizing hormone)

PREDICT Imagine that the anterior pituitary no longer responded to inhibin. How would that affect the ovary?

Although gonadotropic hormones are produced, the ovaries become less responsive to them, and the oocytes in the ovaries begin to degenerate. The ovaries secrete less estrogen and progesterone than previously, and the menstrual cycle becomes irregular and eventually halts.

Women in menopause sometimes experience a sensation of heat (“hot flashes”), probably because of less stable

regulation of blood flow through blood vessels in the skin. Periodic increases of warm blood through these blood vessels may cause the sensation of a hot flash. Other physiological changes associated with menopause include night sweats, mood swings, and weight gain. Although its use is controversial, hormone replacement therapy with estrogen and progesterone relieves symptoms of menopause for many women.

Progesterone is needed to protect the uterus from uterine cancer. If the uterus has been removed by hysterectomy, estrogen alone is used to alleviate menopause symptoms.

In contrast to humans, females of other species maintain their ability to reproduce throughout the lifespan. They do not experience menopause. Researchers have suggested that the infertile postmenopausal period allows older women to help their daughters with grandchildren, increasing their survival rate. This practice may help ensure that the older woman's genes will be transmitted to future generations.

Most mammals have estrous cycles

Only humans and some other primates have menstrual cycles. Most other mammals have *estrous cycles*. Although their reproductive organs and hormones are generally similar, there are some important differences. In animals with estrous cycles, the uterus reabsorbs the thickened lining of the endometrium if conception does not occur. As we have just learned, in animals with a menstrual cycle, the endometrium is expelled during menstruation.

Female animals with estrous cycles are sexually receptive (“in heat”) only during the *estrus phase* of the cycle. The frequency and length of the estrus phase vary. In dogs, the estrus phase typically occurs twice a year and lasts 4 to 13 days. Estrus occurs every 4 to 5 days in rodents. In cats, cycles can occur about every three weeks, and the estrus phase averages 7 days. The resting phase of the cycle is prolonged in the fall and early winter. (Why might that be advantageous?) Animals with estrous cycles typically display physiological and behavioral changes that signal sexual readiness to potential mates.

CHECKPOINT 50.3

- How is oogenesis different from spermatogenesis?
- **PREDICT** What would happen if ovulation occurred but no corpus luteum developed?
- **VISUALIZE** Draw a diagram illustrating hormone interactions during the preovulatory phase. What are the specific actions of FSH? of estrogens?

50.4 Fertilization, Pregnancy, and Birth

LEARNING OBJECTIVE

- 8 Describe the process of human fertilization and summarize the actions of hormones that regulate pregnancy and birth.

Hormones play key roles in preparing the body for fertilization and pregnancy. These signaling molecules are also critical in initiating the birth process.

Fertilization is the fusion of sperm and egg

Fertilization and establishing pregnancy together are referred to as *conception*. After ejaculation into the female reproductive tract, sperm typically remain alive and retain their ability to fertilize an ovum for about 48 hours. However, sperm can survive up to five days in the female reproductive tract. The ovum remains fertile for 12 to 24 hours after ovulation. Therefore, in a very regular 28-day menstrual cycle, heterosexual intercourse during the middle of the cycle is most likely to result in fertilization. However, many women do not have regular menstrual cycles, and many factors can cause an irregular cycle even in women who are generally regular.

When conditions in the vagina and cervix are favorable, sperm begin to arrive at the site of fertilization in the upper oviduct within 30 minutes after ejaculation. At the time of ovulation, when estrogen concentration is high, the cervical mucus has a thin consistency that permits passage of sperm from the vagina into the uterus. During the rest of the menstrual cycle, the cervical mucus is too thick and sticky for sperm to penetrate.

Once sperm enter the uterus, contractions of the muscular uterine wall help transport them. When they reach the oviduct, contractions of smooth muscle in the wall of the oviduct help move sperm toward the egg. The uterine and oviduct contractions are induced by the high estrogen concentration present just before ovulation. Prostaglandins in the semen contribute to this muscle contraction. The sperm's own motility is important, especially in approaching and fertilizing the secondary oocyte. Also, the secondary oocyte is thought to release a compound that attracts the sperm.

When a sperm encounters an egg, openings develop in the sperm acrosome, exposing enzymes that digest a path through the zona pellucida surrounding the secondary oocyte. As soon as one sperm enters the secondary oocyte, changes occur that prevent the entrance of other sperm. As the fertilizing sperm enters, it usually loses its flagellum (**FIG. 50-16**). Sperm entry stimulates the secondary oocyte to complete its second meiotic division. The head of the haploid sperm then swells to form the *male pronucleus* and fuses with the *female pronucleus* to form the diploid nucleus of the zygote. The process of fertilization is described in more detail in Chapter 51 (also see *Inquiring About: Novel Origins*).

If only one sperm is needed to fertilize a secondary oocyte, why are more than a million sperm ejaculated? First, many die as a result of unfavorable pH or phagocytosis by white blood cells and macrophages in the female tract. Only a few hundred succeed in making their way up the correct oviduct and reaching the vicinity of the secondary oocyte. Second, the enzymes released by the acrosomes of many sperm are needed to break down the barriers that surround the secondary oocyte.

When the secondary oocyte is fertilized, development begins while the embryo is still in the oviduct. After three or four days, the progesterone concentration is sufficiently high to induce changes that permit the oviduct to move the embryo to the uterus. The embryo is moved along by muscle

What are some benefits of reproductive technology? About six million couples of reproductive age in the United States are affected by infertility, the inability to achieve conception after using no contraception for at least one year. More than three million infertile couples consult health care professionals each year. Some are helped with conventional treatment, such as with hormone therapy that regulates ovulation or with fertility drugs.

About 30% of infertility cases involve both male and female factors. Male infertility is often attributed to low sperm count. Sperm can be concentrated; alternatively, sperm from a donor can be used to fertilize an egg. Although the sperm donor usually remains anonymous to the prospective birth parents, his genetic qualifications are screened by physicians.

Among the common causes of female infertility are failure to ovulate, production of infertile eggs (common in older women), and oviduct scarring (often caused by pelvic inflammatory disease). Women with blocked oviducts can usually ovulate and incubate an embryo normally but need clinical assistance in getting the young embryo to the uterus.

Many couples are helped with **artificial insemination**, in which a catheter is used to inject sperm directly into the cervix or uterus. Transfer into the uterus is called *intrauterine insemination (IUI)*. More than 600,000 IUI procedures are performed annually, with a success rate of about 10%.

More than 40,000 couples need more sophisticated clinical help. They turn to high-tech, *assisted reproductive techniques (ART)* that have been developed through reproduction and human embryo research. Currently, these techniques are expensive, and the success rate is low, less than one-third. According to the Centers for Disease Control and Prevention (CDC), more than 1% of all infants born in the United States are conceived using ART, including in vitro fertilization, gamete intrafallopian transfer, and zygote intrafallopian transfer.

Using **in vitro fertilization (IVF)**, a woman takes a fertility drug that induces ovulation of several eggs. The eggs are retrieved by needle aspiration through the vagina. These eggs are placed in a dish with sperm, and fertilization takes place in vitro (outside the patient's body). Embryos are cultured for three to five days and then screened for chromosome or gene abnormalities. Healthy ones are transferred into the uterus through the vagina. IVF was first used

in England in 1978 to help a couple who had tried unsuccessfully for several years to have a child. Since that time, thousands of babies have been conceived and born in this way. The success rate of in vitro fertilization is more than 30%; women younger than 35 years have the highest rate of pregnancy, and the rate declines with age.

In *gamete intrafallopian transfer (GIFT)*, a laparoscope (a fiber-optic instrument) is used to guide the transfer of eggs and sperm into a woman's oviduct through a small incision in her abdomen. More than 4000 of these expensive procedures are performed each year, with a success rate of about 28%.

In *zygote intrafallopian transfer (ZIFT)*, the woman's own ova may be used. However, if she does not produce fertile eggs, they can be contributed by a donor (oocyte donation). The ova are fertilized in the laboratory. A laparoscope is used to guide the transfer of the resulting zygotes into the oviduct. The fertilized eggs move through the oviduct into the uterus.

Another novel procedure is **host mothering**. An embryo is removed from its natural mother

and implanted into a female substitute. The foster mother can support the developing embryo either until birth or temporarily until it is implanted again into the original mother or another host. This technique has proved useful to animal breeders. For example, embryos from prize sheep can be temporarily implanted into rabbits for easy shipping by air and then implanted into a host ewe, perhaps one of inferior quality. Host mothering allows an animal with superior genetic traits to produce more offspring than would be naturally possible. This procedure is also used to increase the populations of certain endangered species (see photograph).

Technology is available to freeze the gametes or embryos of many species, including humans, and then transplant them into their donors or into host mothers. Freezing eggs can be an effective strategy for women with cancer who must undergo chemotherapy or for women not yet ready to become parents but who want to preserve young eggs with lower risk for chromosome abnormality. These eggs can be implanted at a later time.

Newborn bongo with its surrogate mother, an eland. As a young embryo, the bongo was transplanted into the eland's uterus, where it implanted and developed. Bongos are a rare and elusive species that inhabits dense forests in Africa. The larger and more common elands inhabit open areas.

contractions and by the cilia lining the oviduct. By the time it enters the uterus, cleavage has occurred and the embryo consists of a ball of about 32 cells. After floating free in the uterus for another three to four days, the embryo (which has

developed into a *blastocyst*) begins to implant in the thick endometrium. Implantation occurs on about the seventh day after fertilization (**FIG. 50-17**). (See Chapter 51 for a discussion of development.)

(a) Sperm release an enzyme that helps disperse the layer of follicle cells (corona radiata) surrounding the secondary oocyte.

(b) After a sperm cell enters, the secondary oocyte completes its second meiotic division, producing an ovum and a polar body.

(c) Pronuclei of sperm and ovum fuse, producing a zygote with the diploid number of chromosomes.

(d) Color-enhanced SEM showing sperm (yellow) clustered on the surface of a human ovum (blue). Only one sperm penetrates the thick surface of the ovum and fertilizes the ovum.

Figure 50-16 Fertilization

Hormones are necessary to maintain pregnancy

Estrogen and progesterone are necessary to maintain conditions required for pregnancy. Estrogen stimulates development of the uterine wall, including the muscle needed to expel the fetus during delivery. Progesterone inhibits uterine contractions so that the fetus is not expelled too soon. Because these hormones also inhibit FSH and LH, new follicles do not develop, and the menstrual cycle stops during pregnancy.

Membranes that develop around the embryo secrete **human chorionic gonadotropin (hCG)**, a peptide hormone that signals the mother's corpus luteum to continue to function. (The presence of hCG in urine or blood is used as an early pregnancy test.) Concentrations of estrogen and progesterone remain high throughout pregnancy. During the first two months, the corpus

luteum secretes almost all the estrogen and progesterone necessary to maintain the pregnancy. During this time, membranes surrounding the embryo, together with uterine tissue, form the **placenta**, the organ of exchange between the mother and developing embryo. By the tenth week of pregnancy, hCG secretion decreases, and the corpus luteum begins to deteriorate. The placenta takes over and secretes large amounts of estrogen and progesterone.

The birth process depends on a positive feedback system

A normal human pregnancy is about 38 weeks long, counting from the day of fertilization, or about 40 weeks from the first day of the last menstrual cycle. The mechanisms that terminate pregnancy and initiate the birth process depend on several hormones. High levels of estrogen secreted by the placenta greatly increase the number of receptors for oxytocin in the uterine wall. As a result, the uterus becomes about one hundred times more responsive to oxytocin, the hormone that stimulates uterine contractions. (Other hormones are involved, but discussion of their roles is beyond the scope of this chapter.)

At the end of pregnancy, the stretching of the uterine muscle by the growing fetus combined with the effects of increased estrogen concentration and oxytocin produce strong uterine contractions. A long series of involuntary contractions of the uterus are experienced as **labor**. Real labor begins when uterine contractions occur in a frequent, regular pattern and cause the cervix to change in preparation for delivery.

Labor can be divided into three stages. During the first stage, which typically lasts 8 to 10 hours, the contractions of the uterus move the fetus toward the cervix, causing the cervix to *dilate* (open) to a maximum diameter of 10 cm (4 in.). The cervix also becomes *effaced*; that is, it thins out so that the fetal head can pass through. During the first stage of labor, the amnion (the membrane that forms a fluid-filled sac

around the embryo/fetus) usually ruptures and releases about a liter of amniotic fluid, which flows out through the vagina.

A positive feedback cycle operates during the birth process. As the baby's head pushes against the cervix, a reflex action causes the uterus to contract. The contraction forces the head against the cervix again, resulting in another contraction, and the positive feedback cycle repeats again and again until the baby descends through the cervix.

During the second stage, which normally lasts from 20 minutes to an hour, the fetus passes through the cervix and vagina and is born, or "delivered" (**FIG. 50-18**). With each uterine contraction, the woman bears down so that the fetus is expelled by the combined forces of uterine contractions and contractions of abdominal wall muscles.

At birth, the baby is still connected to the placenta by the umbilical cord. Contractions of the uterus squeeze much of the fetal blood

Figure 50-17 Events following fertilization

The ovarian and uterine cycles are interrupted when pregnancy occurs. The corpus luteum does not degenerate, and menstruation does not take place. Instead, the wall of the uterus continues to thicken, permitting the embryo to implant and develop within it. (Cleavage is the early series of mitotic divisions that converts the zygote to a multicellular embryo.)

from the placenta into the infant. The cord is tied and cut, separating the child from the mother. (The stump of the cord gradually shrivels until nothing remains but the scar, the *navel*.)

During the third stage of labor, which may last 5 to 30 minutes after the birth, the placenta and the fetal membranes are loosened from the lining of the uterus by another series of contractions and are expelled. At this stage they are collectively called the *afterbirth* because these tissues are expelled from the vagina after the baby has been delivered.

During labor, an obstetrician may administer synthetic oxytocin to increase the contractions of the uterus or may assist delivery with special forceps or a vacuum device. In some women, the opening between the pelvic bones is too small to permit the passage of the baby vaginally. In this situation, the obstetrician performs a *cesarean section* (C-section), a surgical procedure in which the baby is delivered through an incision made in the abdominal and uterine walls. A C-section may also be performed if the baby's position prevents normal delivery or if the baby shows signs of distress.

CHECKPOINT 50.4

- What is the function of hCG?
- **PREDICT** What would happen if the concentration of estrogen and progesterone decreased sharply during early pregnancy? Explain why.

50.5 Human Sexual Response

LEARNING OBJECTIVE

- 9** Describe the physiological changes that take place during human heterosexual intercourse.

Human sexual responses can be varied. Here we describe *heterosexual intercourse*, the type of human sexual activity that has been the focus of the most extensive scientific research. During heterosexual intercourse, the male deposits semen into the upper end of the vagina. The complex structures of the male and female reproductive systems, and the physiological, endocrine, and psychological processes associated with sexual activity, are adaptations that promote fertilization of the secondary oocyte and thus perpetuation of the species.

Sexual stimulation results in two basic physiological responses: (1) vasocongestion, the concentration of blood in reproductive structures as well as in certain other areas of the body; and (2) increased muscle tension. Sexual response includes four phases: sexual excitement, plateau, orgasm, and resolution. The *desire* to have sexual activity may be motivated by fantasies or thoughts about sex. This anticipation can lead to (physical) sexual excitement and a sense of sexual pleasure.

Physiologically, the *sexual excitement phase* involves *vasocongestion*, engorging a tissue with blood, and increased muscle tension. Penile erection is the first male response to sexual excitement. Vasocongestion makes the penis erect so that it can enter the vagina and function in sexual intercourse. In the female, vasocongestion occurs in the vagina,

Courtesy of Dan Atchinson

(a) The mother bears down hard with her abdominal muscles, helping push the baby out. When the head fully appears, the physician or midwife gently grasps it and guides the baby's entrance into the outside world.

Courtesy of Dan Atchinson

(b) Once the head has emerged, the rest of the body usually follows readily. The physician gently aspirates the mouth and pharynx to clear the upper airway of amniotic fluid, mucus, or blood. At this time the newborn takes its first breath.

(d) During the third stage of labor, the placenta is delivered.

Figure 50-18 The birth process

Uterine contractions during labor expel the fetus from the uterus. In about 95% of human births, the baby descends through the cervix and vagina in the head-down position.

clitoris, labia, and breasts. The vaginal epithelium secretes a sticky lubricant. Vaginal lubrication is the female's first response to effective sexual stimulation. During the excitement phase, the vagina lengthens and expands in preparation for receiving the penis.

If erotic stimulation continues, sexual excitement heightens to the *plateau phase*. Vasocongestion and muscle tension increase markedly. In both sexes, heart rate, blood pressure, and respiration rate increase. Sexual intercourse is usually initiated during the plateau phase. The penis creates friction as it is moved inward and outward in the vagina, in actions referred to as pelvic thrusts. Physical sensations resulting from this friction and the psychological experience of emotional intimacy lead to **orgasm**, the intense physical pleasure that is the climax of sexual excitement. In the female, stimulation of the clitoris heightens the sexual excitement that leads to orgasm.

Although it lasts only a few seconds, orgasm is the phase of maximum sexual tension and its release. Musculoskeletal contractions occur, especially in the reproductive structures. Heart rate and respiration more than double, and blood pressure increases markedly, just before and during orgasm. In both sexes, orgasm is marked by rhythmic contractions of the muscles of the pelvic floor and reproductive structures. These muscular contractions continue at about 0.8-second intervals for several seconds. After the first few contractions, their intensity decreases, and they become less regular and less frequent.

The male orgasm is marked by *ejaculation* of semen from the penis. Semen is typically ejaculated in about seven spurts that accompany the rhythmic contractions. No fluid ejaculation accompanies orgasm in the female. Orgasm is followed by the *resolution phase*, a state of well-being during which the body is restored to its unstimulated state.

CHECKPOINT 50.5

- What physiological changes take place during the sexual response cycle?

50.6 Birth Control Methods and Abortion

LEARNING OBJECTIVE

- 10** Compare the modes of action, effectiveness, advantages, and disadvantages of the methods of birth control discussed, including sterilization and emergency contraception; distinguish between spontaneous and induced abortions.

Worldwide, there are about 135 million births per year. Population experts estimate that more than one-fourth of them are unplanned. An estimated 50 million induced abortions are performed annually. Although most couples worldwide might agree that it is best to have babies by choice rather than by chance, many do not have contraceptives available to them. (About one-fourth of women in developing countries have an unmet need for contraception.) Women who do not have access to modern contraceptives account for 84% of unintended pregnancies.

In the United States, nearly half of all pregnancies are unintended. Teen pregnancy is a particularly serious problem. Many teens lack the knowledge and means of protecting themselves from unwanted pregnancy. Not surprisingly, about 80% of teen pregnancies are unplanned. About 30% of teen pregnancies end in abortion. According to the Centers for Disease Control and Prevention, in 2015, 229,715 babies were born to teenagers aged 15 to 19 years. (This represents a birth rate of 22.3 per 1000 women in this age group.) These numbers represent a decline in teen birth rate, apparently due to fewer teens engaging in sexual activity and the greater availability of effective birth control methods.

Many birth control methods are available

When a fertile, heterosexually active woman uses no form of birth control, her chances of becoming pregnant during the course of a year are about 85%. Any method for deliberately separating sexual intercourse from reproduction is **contraception** (literally, “against conception”).

Since ancient times, humans have searched for effective methods of preventing fertilization and pregnancy. Of course, fertilization can be avoided by abstaining from sexual intercourse, particularly around the time of ovulation. This cyclical temporary abstinence is called the *rhythm method* or *natural family planning*. Because the time of ovulation is difficult to determine, the rhythm method has a high failure rate (about 25%). Scientists continue to develop a variety of contraceptives with a high percentage of reliability. Some common methods of birth control are described in

the following paragraphs and in **TABLE 50-3**. Oral contraceptives, intrauterine devices (IUDs), and female sterilization account for more than two-thirds of all contraception practiced worldwide.

Most hormonal contraceptives prevent ovulation

Hormonal contraceptives include oral contraceptives, contraceptive patches, rings, implants, and injectable contraceptives. More than 80 million women worldwide (more than 11 million in the United States alone) use oral contraceptives. When used as prescribed, oral contraceptives are about 99.7% effective in preventing pregnancy. They are also used to regulate menstrual cycles and help with symptoms associated with menstruation. The most common preparations are combinations of *progestins*, which are synthetic progesterones, and synthetic estrogen. (Natural hormones are destroyed by the liver almost immediately, but synthetic ones are chemically modified during production so that they can be absorbed effectively and metabolized slowly.) In a typical regimen, a woman takes one pill each day for about three weeks. Then, for one week she takes a sugar pill that allows menstruation to occur as a result of the withdrawal of the hormones. One type of oral contraceptive works on a 91-day regimen, reducing menstruation to four times per year. Other new oral contraceptives are being marketed as methods to manipulate menstrual cycles so that menstruation is shorter.

Oral contraceptives prevent ovulation. When postovulatory levels of ovarian hormones are maintained in the blood, the body is tricked into responding as though conception has occurred. The pituitary gland is inhibited and does not produce the surge of LH that stimulates ovulation.

Studies suggest that women older than age 35 who smoke or have other risk factors, such as untreated hypertension, should not take oral contraceptives. Women in this category who take oral contraceptives have an increased risk of death from stroke and myocardial infarction. Low-dose oral contraceptive pills appear safe for nonsmokers up to the time of menopause. Oral contraceptives are linked to deaths in about 3 per 100,000 users per year, which compares favorably with the death rate of about 9 per 100,000 pregnancies.

Trends in contraception are geared toward convenience and improved compliance. The birth control patch (Ortho Evra) delivers estrogen and progestin through the skin. Another approach is a thin, flexible plastic ring (NuvaRing) that women can flatten like a rubber band and insert into the vagina once a month. The ring releases progestin and estrogen in the amounts present in low-dose birth control pills. These types of contraception are convenient because they do not require a daily regimen, while maintaining a regular, predictable menstrual cycle.

Injectable progestin (Depo-Provera) is injected intramuscularly every three months. It prevents ovulation by suppressing anterior pituitary function; it also thickens the cervical mucus (which makes it more difficult for the sperm to reach the egg). Implanon and Nexplanon are implant systems. Each consists of a single plastic progestin rod (the size of a cardboard matchstick). The progestin is released over a three-year period. Many consider these implants the most effective birth control methods available.

Table 50-3 Selected Contraceptive Methods

Method	Percent Effective When Used Correctly	Mode of Action	Advantages	Disadvantages
Oral contraceptives (combined estrogen and progestin pill)	>99%	Inhibit ovulation	Highly effective; regulate menstrual cycle	Requires women to remember to take daily pill; should not be used by women over age 35 who smoke or have other risk factors
Contraceptive implants (progestin)	>99%	Prevent ovulation	Can be used for three years	May cause irregular vaginal bleeding
Injectable contraceptives (Depo-Provera)	97%–>99%	Inhibit ovulation	Effective; long-lasting	Irregular vaginal bleeding
Intrauterine devices (IUDs) (T-shaped plastic devices)	>99%		Provide continuous protection for several years; safe	Increase menstrual cramps and symptoms of endometriosis
One type releases progestins		Progestin thickens cervical mucus, preventing sperm from reaching ovum		
Second type has copper component		Copper stimulates inflammatory response in uterus		
Male condom	85% as commonly used; 98% with correct use	Mechanically prevents sperm from entering vagina	No side effects; some protection against STIs, including HIV	Slightly decreased sensation for male; could break
Rhythm method*	75% as commonly used	Abstinence or using condom during fertile period	No known side effects	Certain medications, such as antidepressants, anxiolytics, NSAIDs, and certain antibiotics may affect timing of ovulation
Withdrawal (coitus interruptus)	73% as commonly used	Male withdraws penis from vagina prior to ejaculation	No side effects	Not reliable; sperm in fluid secreted before ejaculation may be sufficient for conception
Sterilization				
Vasectomy	>99% after three months of semen evaluation		Most reliable male method	Requires surgery; considered permanent
Tubal ligation	>99%		Most reliable female method	Requires surgery; permanent
Chance of NOT becoming pregnant when NOT using contraception	About 15% (that is, about 85% become pregnant)			

SOURCES: World Health Organization, Centers for Disease Control and Prevention, and Guttmacher Institute.

* There are several variations of the rhythm method. For those who use the calendar method alone, the effective rate is about 65%. However, if body temperature is taken daily and careful records are kept (temperature rises after ovulation), the success rate can be increased. When women use some method to determine time of ovulation and have intercourse *only* more than 48 hours *after* ovulation, the effective rate can be even further increased.

Intrauterine devices are widely used

Contraceptive implants and IUDs are long-acting, reversible contraception (LARC). *The intrauterine device (IUD)* is the most widely used method of reversible contraception in the world, used by an estimated 90 million women. In the United States, however, only about 4 million women (about 10% of contraception users) use IUDs. The IUD is a small device that is inserted into the uterus by a health professional. The advantages of IUDs are that they are safe, about 99% effective, and completely reversible. IUDs can also improve the symptoms of a woman's menstrual periods. Disadvantages of the IUD include uterine cramping and bleeding in a small percentage of women.

IUDs are small, plastic T-shaped devices. Each releases a very small amount of a progestin hormone (levonorgestrel)

onto the inner wall of the uterus. The progestin thickens the cervical mucus, which prevents sperm from reaching the secondary oocyte. Some brands of IUD (Mirena, Kyleena) can be left in place for up to five years. Another type of IUD (Skyla) contains less progestin; it can be left in place for about three years.

The Copper T IUD (ParaGard) contains no hormones. It is wrapped in copper, which stimulates an inflammatory response in the uterus. As a result, sperm are unable to reach the secondary oocyte. The Copper T IUD can be left in place for up to 10 years.

The IUD apparently prevents fertilization in a number of ways. Some IUDs cause the cervical mucus to thicken, which impedes passage of sperm into the uterus. The copper in an IUD apparently also reduces the ability of sperm to fertilize the egg. In addition, white blood cells mobilized in response to the foreign body (IUD) in the uterus may produce substances toxic to sperm.

Barrier methods of contraception include the diaphragm and condom

The *contraceptive diaphragm* mechanically blocks the passage of sperm from the vagina into the cervix. It is covered with spermicidal jelly or cream and inserted just prior to sexual intercourse. The contraceptive diaphragm has been largely replaced by more sophisticated birth control methods.

The *condom* is also a mechanical method of birth control. The only contraceptive device currently sold for men, the condom provides a barrier that contains the semen so that sperm cannot enter the female tract. The latex condom provides some protection against infection with HIV and other sexually transmitted infections (STIs).

The female condom is a strong, soft, polyurethane pouch, or sheath, inserted in the vagina before sexual intercourse. When used correctly, it provides protection against both pregnancy and sexually transmitted infections.

Emergency contraception is available

Emergency contraception is after-the-fact contraception for rape victims and others who have had unprotected sexual intercourse. Emergency contraception pills prevent fertilization or ovulation. They decrease the probability of pregnancy by about 89%. Although they are often called morning-after pills, emergency contraception pills can actually be taken up to four days after unprotected intercourse. The use of emergency contraception has significantly reduced the number of abortions. Emergency contraception is available to people of all ages without a prescription.

The most common types of emergency contraception are *progestin* pills, known as Plan B, and combination progestin-and-estrogen pills. Another pill, called “Ella,” is also available for emergency contraception, but requires a prescription. Ella contains a nonhormonal medication (ulipristal) that works by preventing or postponing ovulation. This medication can be taken up to 120 hours (5 days) after unprotected intercourse. A less common type of emergency contraception is insertion of a copper IUD within five days of unprotected intercourse. This method is about 99% effective in preventing pregnancy.

Sterilization renders an individual incapable of producing offspring

Sterilization is the only method of contraception not affected by failure to use a contraceptive method correctly. According to the World Health Organization, male sterilization is the most common contraceptive method in the world. It accounts for one-third of all contraceptive use. Interestingly, nine in ten sterilized persons are women.

Male sterilization is performed by vasectomy *Vasectomies* are performed using a local anesthetic. The physician

makes a small incision on each side of the scrotum. Then each vas deferens is cut and its ends sealed so that they cannot grow back together (**FIG. 50-19a**). Because testosterone secretion is not affected, vasectomy does not affect masculinity. Sperm continue to be produced, although at a much slower rate, and are destroyed by macrophages in the testes. No change in amount of semen ejaculated is noticed because sperm account for very little of the semen volume.

By surgically reuniting the ends of the vasa deferentia, surgeons can successfully reverse sterilization in about 50% of males. However, some sterilized men eventually develop antibodies against their own sperm. These men remain sterile even after their vasectomies have been surgically reversed. Therefore, fertility rates are low (about 30%) for men who undergo vasectomy reversal after ten or more years.

An alternative to vasectomy reversal is the storage of frozen sperm in sperm banks. Such banks have been established throughout the United States. If the male should decide to father another child after he has been sterilized, he “withdraws” his sperm to artificially inseminate his mate. However, sperm do not always survive freezing, and even if they remain viable, there may be an increased risk of genetic defects.

Tubal sterilization blocks the oviducts In the United States, **tubal sterilization** is one of the most common means of birth control. As with the male, hormone balance and sexual performance of the female are not affected by sterilization. A surgeon performs this procedure either by laparoscopy or by open incision. Tubal sterilization is often performed at the time of a C-section. During female sterilization, the tubes are cauterized, clipped, or tied off (**FIG. 50-19b**).

More recently, tubal sterilization can be accomplished without an incision. Essure is a nonsurgical, permanent sterilization procedure in which small, flexible inserts are placed in the uterine tubes. Small coils are inserted through the vagina, so no incision is needed. The Essure apparatus causes tissue to grow around the insert. After about three months, this tissue growth blocks sperm from reaching an egg.

Figure 50-19 Sterilization

Future contraceptives may control regulatory peptides

Ideal contraceptives have not yet been developed. Among the issues that must be considered in developing contraceptives are safety, effectiveness, cost, convenience, and ease of use. Risks of cancer, birth defects in case the method fails and the woman becomes pregnant, permanent infertility, and side effects such as menstrual abnormalities must be minimized.

Investigators are currently exploring methods for interfering with sperm motility or with fertilization. For example, an injectable gel (Vasalgel) that blocks sperm passage through the vas deferens has been tested in primates. (Trials in humans will probably be taking place by the time you read these words.)

It is likely that current methods of contraception will be replaced by more sophisticated molecular methods within the next several years. Some researchers predict that future contraceptive methods will control regulatory peptides and the genes that code for them. For example, the genes that code for certain hormone signals could be interrupted. Another approach being studied is development of contraceptive vaccines that would stimulate the immune system to produce antibodies against hCG or some other protein essential to reproduction.

Abortions can be spontaneous or induced

Abortion is the termination of pregnancy that results in the death of the embryo or fetus. *Spontaneous abortions* (commonly referred to as miscarriages) occur without intervention. Embryos that are spontaneously aborted are frequently abnormal. *Induced abortions* are performed deliberately either for therapeutic reasons or as a means of birth control. *Therapeutic abortions* are performed when the mother's life is in danger or when there is reason to suspect that the embryo is grossly abnormal.

Abortions are sometimes used as a means of birth control. More than 40 million induced abortions are performed each year (more than 1 million in the United States). Many first-trimester abortions (those performed during the first three months of pregnancy) are performed by administering drugs that interrupt the pregnancy and induce expulsion of the embryo. The drug RU-486 (mifepristone) binds competitively with progesterone receptors in the uterus but does not activate them. Because the normal actions of progesterone are blocked, the endometrium breaks down, and uterine contractions occur. These conditions prevent implantation of an embryo. Prostaglandins may then be administered to induce the uterine contractions that expel the embryo. Misoprostol (Cytotec) is a synthetic prostaglandin also used to terminate pregnancies. During a surgical abortion, the cervix is dilated, and a suction aspirator is inserted into the uterus. The embryo and other products of conception are evacuated.

After the first trimester, abortions are performed mainly because of fetal abnormalities or maternal illness. The method most commonly used is dilation and evacuation. The cervix is dilated, a forceps-type instrument is used to remove the fetus, and suction is used to aspirate the remaining contents of the uterus. Drugs such as prostaglandins are also used to induce labor in second-trimester abortions.

When abortions are performed by skilled medical personnel, they are relatively safe. The risk of death increases with the length of the pregnancy. In the United States, the mortality rate is less than 0.3 per 100,000 abortions performed at or before 8 weeks. Abortions performed at 18 weeks or later have a mortality rate of 6.7 per 100,000.¹ In countries where abortion is illegal (and unsafe), the death rate is as high as 450 per 100,000. These statistics can be contrasted with the death rate from pregnancy and childbirth of about 9 per 100,000. The World Health Organization estimates that about 13% of all maternal deaths result from poorly performed, illegal abortions.

CHECKPOINT 50.6

- How do hormone methods of contraception work?
- **PREDICT** The use of which types of contraception would have the greatest effect on the number of unwanted pregnancies?
- What is a spontaneous abortion? a therapeutic abortion?

50.7 Sexually Transmitted Infections

LEARNING OBJECTIVE

- 11** Identify common sexually transmitted infections and describe their symptoms, effects, and treatments.

Sexually transmitted infections (STIs), also called *sexually transmitted diseases (STDs)*, are the most prevalent communicable diseases in the world next to the common cold. The World Health Organization has estimated that more than 350 million new curable sexually transmitted infections occur each year. More than 62 million people are infected each year with *gonorrhea*, and more than 12 million are infected with *syphilis*. Globally, more than 37 million people are living with HIV, and more than 35 million have died of AIDS since 1981 (discussed in Chapter 45).

In the United States, more than 110 million people are currently living with an STI, and more than 20 million people (including 3 million teens) are diagnosed with new STI infections each year. One in three sexually active young people will acquire an STI by age 24. These young people account for 50% of all new STIs. Some common STIs are described in **TABLE 50-4**. (See Chapter 45 for a discussion of HIV.)

Human papillomavirus (HPV) is one of the two most common STIs in the United States. An estimated 14 million people in the United States are infected with HPV each year. In most infected individuals, the immune system destroys or suppresses the virus before it causes serious health problems. However,

¹ Data are from the Guttmacher Institute.

HPV can cause abnormal Pap smears and is the main cause of cervical cancer. Some strains of HPV cause genital warts.

Vaccines (Gardasil and Cervarix) prevent infection by several harmful HPV strains. Health professionals anticipate that use of these vaccines will lead to the decline of genital warts and cervical cancer. For the vaccine to be most effective, individuals should be vaccinated before they become sexually active. These vaccines are recommended for both females and males at ages 9 through 14.

Chlamydia is the most commonly reported STI in the United States. This STI is transmitted by having vaginal, anal, or oral sex with someone who has chlamydia. Most individuals infected with chlamydia do not know it because this disease causes no symptoms in about 50% of infected men and 75% of infected women. Infected men may notice a discharge from the penis, and infected women may have a vaginal discharge. In women, the infection can spread and cause

pelvic inflammatory disease (PID). This serious infection leads to infertility in about 20% of infected women.

About 16% of individuals age 14 to 49 years old are infected with **genital herpes**. This STI is caused by a herpes virus and can be transmitted by genital contact or by oral sex. Most infected individuals do not know they have the infection because it causes minimal symptoms, or no symptoms. When outbreaks occur, symptoms may include blisters around the genital area.

 CHECKPOINT 50.7

- What are the two most common STIs in the United States?
- **CONNECT** What is PID? What causes it?

Table 50-4 Some Common Sexually Transmitted Infections

Disease and Causative Organism	Course of Disease	Treatment
Human papillomavirus (HPV; about 30 strains of HPV can infect reproductive organs)	Causes abnormal Pap smears and cervical cancer; some strains cause genital warts	Immune modifiers; interferon; vaccines available
Chlamydia (<i>Chlamydia trachomatis</i> , a bacterium)	Discharge and burning with urination, or asymptomatic; men ages 15–30 with multiple sex partners are most at risk; in women can cause pelvic inflammatory disease (PID), infection of reproductive organs and pelvic cavity that may lead to sterility (>15% of cases)	Antibiotics
Genital herpes (herpes simplex type 2 virus)	Symptoms may be absent or minimal; when they occur, symptoms include painful blisters in genital area that develop into ulcers; symptoms recur periodically; threat to fetus or newborn infant; can be contracted via oral sex	No effective cure; some drugs may shorten outbreaks or reduce severity; medication can be taken to prevent outbreak
Acquired immunodeficiency syndrome (AIDS)* (caused by human immunodeficiency virus, HIV)	First few weeks: no symptoms or influenza-like symptoms (fever, headache, rash, sore throat); later, other symptoms may include swollen lymph glands, fever, night sweats, weight loss; depressed immunity may lead to pneumonia, rare forms of cancer, and other diseases	No effective cure; a variety of drugs reduce symptoms and prolong life
Trichomoniasis (a protozoan)	Itching, discharge, soreness; can be contracted from dirty toilet seats and towels; may be asymptomatic in males	Metronidazole (an antibiotic)
“Yeast” infections (genital candidiasis; <i>Candida albicans</i>)	Irritation, soreness, discharge; especially common in females; rare in males; can be acquired nonsexually	Antifungal drugs
Gonorrhea (<i>Neisseria gonorrhoeae</i> , a gonococcus bacterium)	Bacterial toxin may produce redness and swelling at infection site; symptoms in males are painful urination and discharge of pus from penis; in about 60% of infected women, no symptoms initially; can spread to epididymis (in males) or oviducts and ovaries (in females), causing sterility; can cause widespread infection; damage to heart valves, meninges, and joints	Antibiotics, but strains of drug-resistant gonorrhea are an urgent public health issue
Syphilis (<i>Treponema pallidum</i> , a spirochete bacterium)	Incidence rising in the U.S.; bacteria enter body through defect in skin; primary chancre (small, painless ulcer) at site of initial infection; highly infectious at this stage; secondary stage, widespread rash and influenza-like symptoms; scaly lesions may occur that are highly infectious; latent stage that follows can last 20 years; eventually, lesions called gummae may form that damage liver, brain, bone, or spleen	Penicillin

* AIDS was discussed in Chapter 45.

Summary: Focus on Learning Objectives

50.1 Asexual and Sexual Reproduction (page 1075)

1 Compare the benefits of asexual and sexual reproduction, and describe each mode of reproduction, giving specific examples.

- In **asexual reproduction**, a single parent produces offspring with a set of genes identical to its own. Asexual reproduction is energy efficient. It is most successful in stable environments.
- Three types of asexual reproduction are budding, fragmentation, and parthenogenesis. In **budding**, a part of the parent's body grows and separates from the rest of the body. In **fragmentation**, the parent's body may break into several pieces, and each piece can develop into a new animal. In **parthenogenesis**, an unfertilized egg develops into an adult.
- In **sexual reproduction**, offspring are produced by the fusion of two types of gametes: **ovum** and **sperm**. When a sperm and egg fuse, a fertilized egg, or **zygote**, is produced. Sexual reproduction promotes genetic variety and is especially adaptive in unstable, changing environments.
- In **external fertilization**, mating partners typically release eggs and sperm into the water simultaneously. In **internal fertilization**, the male delivers sperm into the female's body.
- In **hermaphroditism**, a single individual produces both eggs and sperm.

50.2 Human Reproduction: The Male (page 1077)

2 Relate the structure of each organ of the human male reproductive system to its function.

- The human male reproductive system includes the testes, which produce sperm and testosterone; a series of conducting ducts; accessory glands; and the penis.
- The **testes**, housed in the **scrotum**, contain the **seminiferous tubules**, where **spermatogenesis** (sperm production) takes place. The **interstitial cells** in the testes secrete testosterone.
- Sperm complete their maturation and are stored in the **epididymis** and **vas deferens**. During **ejaculation**, sperm pass from the vas deferens to the **ejaculatory duct** and then into the **urethra**, which passes through the penis.

- The **penis** consists of three columns of **erectile tissue**: two **cavernous bodies** and one **spongy body**, which surrounds the urethra. When its erectile tissue becomes engorged with blood, the penis becomes erect and functions as the copulatory organ.

3 Trace the passage of sperm cells through the human male reproductive system from their origin in the seminiferous tubules to their expulsion from the body in the semen; include a description of spermatogenesis.

- Spermatogenesis takes place in the seminiferous tubules of the testes. **Spermatogonia** divide by mitosis; some differentiate and become **primary spermatocytes**, which undergo **meiosis**. The first meiotic division produces two **secondary spermatocytes**. In the second meiotic division, each secondary spermatocyte produces two **spermatids**. Each spermatid differentiates to form a mature sperm.
- The head of a sperm consists of the nucleus and a cap, or **acrosome**, containing enzymes that help the sperm penetrate the egg.
- Sperm pass in sequence through the seminiferous tubules of the testis, epididymis, vas deferens, ejaculatory duct, and urethra.
- Each ejaculate of semen contains about 200 million sperm suspended in the secretions of the **seminal vesicles** and **prostate gland**. The **bulbourethral glands** release a mucous secretion.

4 Describe endocrine regulation of reproduction in the human male.

- **Testosterone** establishes and maintains male *primary sex characteristics*, growth of reproductive organs, and spermatogenesis. Testosterone also stimulates development of **secondary sex characteristics** at puberty: growth of facial and body hair, muscle development, and deepened voice.
- Endocrine regulation of male reproduction involves the hypothalamus, pituitary gland, and testes. The hypothalamus secretes **gonadotropin-releasing hormone (GnRH)**, which stimulates the anterior pituitary gland to secrete the gonadotropic hormones: **follicle-stimulating hormone (FSH)** and **luteinizing hormone (LH)**.
- FSH, LH, and testosterone directly or indirectly stimulate sperm production. LH stimulates the interstitial cells of the testes to produce testosterone. FSH stimulates the Sertoli cells to produce (1) **androgen-binding protein (ABP)**, which binds to testosterone and concentrates it; and (2) **inhibin**, a hormone that inhibits FSH secretion.

50.3 Human Reproduction: The Female (page 1082)

5 Relate the structure of each organ of the human female reproductive system to its function.

- The **ovaries** produce gametes and the steroid hormones **estrogens** and **progesterone**. Fertilization takes place in the **oviducts** (uterine tubes).
- The **uterus** serves as an incubator for the developing embryo. The epithelial lining of the uterus, the **endometrium**, thickens each month in preparation for possible pregnancy. The lower part of the uterus, the **cervix**, extends into the vagina.

- The **vagina** receives the penis during heterosexual intercourse and is the lower part of the birth canal. The **vulva** includes the *labia majora*, *labia minora*, *vestibule* of the vagina, **clitoris**, and *mons pubis*.
- The breasts function in **lactation**, production of milk for the young. Each breast consists of 15 to 20 lobes of glandular tissue. The hormone **prolactin** stimulates milk production; **oxytocin** stimulates ejection of milk from the alveoli into the ducts, making it available to the nursing infant.

6 Trace the development of a human egg and trace its passage through the female reproductive system until it is fertilized.

- **Oogenesis** takes place in the ovaries. **Oogonia** differentiate into **primary oocytes**. A primary oocyte and the **granulosa cells** surrounding it make up a **follicle**.
- As the follicle grows, connective tissue cells surrounding the granulosa cells form a layer of **theca cells**. As the follicle matures, the primary oocyte undergoes the first meiotic division, giving rise to a **secondary oocyte** and a **polar body**.
- During **ovulation**, the secondary oocyte is ejected from the ovary and enters one of the paired oviducts, where it may be fertilized. The part of the follicle remaining in the ovary develops into a **corpus luteum**, a temporary endocrine gland.

7 Describe the endocrine regulation of reproduction in the human female and identify key events of the menstrual cycle, such as ovulation and menstruation.

- The hypothalamus, pituitary gland, and ovaries secrete hormones that regulate female reproduction. The first day of the **menstrual cycle** is marked by the beginning of menstrual bleeding. Ovulation occurs at about day 14 in a typical 28-day menstrual cycle.
- During the *preovulatory phase*, gonadotropin-releasing hormone (GnRH) from the hypothalamus stimulates the anterior lobe of the pituitary to secrete follicle-stimulating hormone (FSH) and luteinizing hormone (LH). FSH stimulates follicle development and stimulates the granulosa cells to produce estrogen. LH stimulates theca cells to multiply and produce androgens, which are converted to estrogen.

- Estrogen is responsible for primary and secondary female sex characteristics and stimulates development of the endometrium.
- After the first week, only one follicle continues to develop. Although at relatively low concentration, estrogen inhibits FSH secretion by negative feedback. Granulosa cells produce inhibin, which also inhibits FSH secretion.
- During the late *preovulatory phase*, estrogen concentration peaks. Through a positive feedback mechanism, estrogen signals the anterior pituitary to secrete LH. This hormone stimulates final maturation of the follicle and stimulates ovulation.
- During the *postovulatory phase*, LH promotes development of the corpus luteum. The corpus luteum secretes progesterone and estrogen, which stimulate final preparation of the uterus for pregnancy. During the postovulatory phase, progesterone, along with estrogen, inhibits secretion of GnRH, FSH, and LH.
- If fertilization does not occur, the corpus luteum degenerates, concentrations of estrogen and progesterone in the blood fall, and **menstruation** occurs.

50.4 Fertilization, Pregnancy, and Birth (page 1091)

8 Describe the process of human fertilization and summarize the actions of hormones that regulate pregnancy and birth.

- Human **fertilization** is the fusion of a secondary oocyte and a sperm to form a zygote. The processes of fertilization and establishing pregnancy together are called *conception*.
- If the secondary oocyte is fertilized, development begins and the embryo implants in the uterus. Membranes that develop around the embryo secrete **human chorionic gonadotropin (hCG)**, a hormone that maintains the corpus luteum. During the first two to three months of pregnancy, the corpus luteum secretes the large amounts of estrogen and progesterone needed to maintain pregnancy. After three months, the **placenta**, the organ of exchange between mother and embryo, assumes this function.
- Several hormones, including estrogen, oxytocin, and prostaglandins, regulate the birth process. Labor can be divided into three stages; the baby is delivered during the second stage.

50.5 Human Sexual Response (page 1094)

9 Describe the physiological changes that take place during human heterosexual intercourse.

- *Vasocongestion*, engorgement of a tissue with blood, and increased muscle tension, are physiological responses to sexual stimulation. The phases of the human sexual response include *sexual excitement*, *plateau*, **orgasm**, and *resolution*.

50.6 Birth Control Methods and Abortion (page 1096)

10 Compare the modes of action, effectiveness, advantages, and disadvantages of the methods of birth control discussed, including sterilization and emergency contraception; distinguish between spontaneous and induced abortions.

- Effective methods of **contraception** include *hormonal contraceptives*, such as oral contraceptives and injectable progestin; *intrauterine devices (IUDs)*; *condoms*; *contraceptive diaphragms*; and **sterilization** (*vasectomy* in the male and *tubal sterilization* in the female); see Table 50-3. Emergency contraception can be used to prevent unwanted pregnancy after rape or unprotected intercourse.

- **Spontaneous abortions** (miscarriages) occur without intervention. **Induced abortions** include *therapeutic abortions*, performed when the mother's health is in danger or when the embryo is thought to be grossly abnormal. Abortions are also induced as a means of birth control.

50.7 Sexually Transmitted Infections (page 1099)

- 11 Identify common sexually transmitted infections and describe their symptoms, effects, and treatments.**

- Among the common types of *sexually transmitted infections (STIs)* are *chlamydia* (which causes *pelvic inflammatory disease*), *human papillomavirus (HPV)*, *genital herpes*, *gonorrhea*, *syphilis*, and **human immunodeficiency virus (HIV)** (see Table 50-4).

Test Your Understanding

Know and Comprehend

- Hermaphroditism (a) is a form of asexual reproduction (b) occurs when an unfertilized egg develops into an adult animal (c) is a form of sexual reproduction in which an animal produces both eggs and sperm (d) typically involves self-fertilization (e) typically requires only a male animal
- In contrast to asexual reproduction, sexual reproduction (a) is a faster way to produce offspring (b) is more efficient (c) results in more offspring (d) is less efficient at removing harmful mutations from a population (e) increases genetic variety among members of a population
- The seminiferous tubules (a) are the site of spermatogenesis (b) produce most of the seminal fluid (c) empty directly into the vas deferens (d) are located within the cavernous body (e) receive fluid from the bulbourethral glands
- Which of the following cells is haploid? (a) primary oocyte (b) secondary oocyte (c) oogonium (d) cells of the corpus luteum (e) follicle cell
- The corpus luteum (a) is surrounded by ova (b) degenerates if fertilization occurs (c) develops in the preovulatory phase (d) is maintained by prostaglandins (e) serves as a temporary endocrine gland
- After ovulation, the secondary oocyte enters the (a) oviduct (b) corpus luteum (c) cervix (d) ovary (e) vagina
- Hormonal contraceptives (a) prevent ovulation (b) decrease estrogen concentration in the blood (c) are not as effective as barrier methods of contraception (d) decrease risk of STIs (e) a and b only
- Pelvic inflammatory disease is commonly caused by (a) syphilis (b) gonorrhea (c) genital herpes (d) HIV (e) chlamydia

Apply and Analyze

- Arrange the following stages into the correct sequence:
1. spermatid 2. spermatogonium 3. sperm 4. secondary spermatocyte 5. primary spermatocyte (a) 2, 1, 3, 4, 5 (b) 5, 1, 3, 4, 2 (c) 1, 3, 4, 2, 5 (d) 2, 5, 4, 1, 3 (e) 1, 4, 3, 2, 5
- Which sequence best describes the passage of sperm?
1. urethra 2. vas deferens 3. epididymis 4. ejaculatory duct 5. seminiferous tubules (a) 3, 1, 2, 4, 5 (b) 1, 3, 2, 4, 5 (c) 5, 3, 2, 4, 1 (d) 1, 3, 4, 2, 5 (e) 3, 1, 4, 2, 5

- 11. VISUALIZE** Label the diagram.

51 Animal Development

KEY CONCEPTS

- 51.1** The development of form requires not only cell division and growth, but also cell determination and cell differentiation as well as pattern formation and morphogenesis.
- 51.2** Fertilization includes contact and recognition between egg and sperm, regulated sperm entry, activation of the fertilized egg, and fusion of egg and sperm pronuclei.
- 51.3** Cleavage, a series of rapid cell divisions without growth, provides cellular building blocks for development.
- 51.4** Gastrulation establishes ectoderm, mesoderm, and endoderm; each gives rise to specific types of tissues.
- 51.5** One of the earliest events in organogenesis (organ development) is neurulation, the origin of the central nervous system.
- 51.6** Extraembryonic membranes (amnion, chorion, allantois, and yolk sac) have evolved in terrestrial vertebrates as adaptations to reproduction on land.
- 51.7** Human development follows the pattern for placental mammals.

PHOTO: Human embryo at 7 to 8 weeks of development. The embryo, enclosed in its amniotic sac, is about 2.5 cm (1.0 in.) long. Note the umbilical cord attached to the placenta (*upper left*) and the balloon-like remnant of the yolk sac (*upper right*). The limbs and one of the eyes are visible. Dr. G. Moscoso/Science Source

Development includes all the changes that take place during the entire life of an individual. In this chapter, however, we focus mainly on the fertilization of the egg to form a zygote and the subsequent development of the young animal before birth or hatching.

Just how does a microscopic, unicellular zygote give rise to the bones, muscles, brain, and other structures of a complex animal? The zygote divides by mitosis, forming an **embryo** that subsequently undergoes an orderly sequence of cell divisions. In animals, growth (i.e., increase in mass) occurs primarily by an increase in the number of cells, but it also occurs by an increase in cell size, as in fat cells. Although the very early embryo usually does not grow, later cell divisions typically contribute to growth. However, by itself cell division, which is governed by a genetic program that interacts with environmental signals (see Chapter 10), would produce only a formless heap of similar cells. We therefore begin this chapter with a discussion of the fundamental processes introduced in Chapter 17 that contribute to the development of form: cell determination and cell differentiation; and pattern formation and morphogenesis.

The photograph shows a human embryo enclosed in its fluid-filled amniotic cavity and attached to its yolk sac. In this chapter you have an opportunity to compare and contrast the sequences of developmental events in several different animals in addition to humans. Researchers have chosen these model organisms because they have certain desirable characteristics. For example, the embryos of certain types of animals, such as echinoderms and amphibians, can be obtained in large quantities, which facilitates studies in which biochemical changes are correlated with developmental landmarks. The embryos of echinoderms are particularly easy to observe because they are transparent. The embryos of echinoderms, amphibians, and birds are easily grown in the laboratory. As you read, note the intimate

inter-relationships among the sequential developmental processes as well as the fundamental similarities among the early developmental events in the different animal groups featured. Many decades of painstaking investigations on these similarities became the foundations of the science of evolutionary developmental biology, popularly known as **Evo Devo**, introduced in Chapters 17 and 30.

51.1 Development of Form

LEARNING OBJECTIVES

- 1 Analyze the relationship between cell determination and cell differentiation and between pattern formation and morphogenesis.
- 2 Relate differential gene expression to nuclear equivalence.

The development of the form of an animal is a consequence of a balanced combination of several fundamental processes that go beyond cell division and growth: cell determination and cell differentiation, and pattern formation and morphogenesis.

As embryonic development proceeds, cell division gives rise to increasing numbers of cells, which serve as the building blocks of development. At various times, certain cells become biochemically and structurally specialized to carry out specific functions through a process known as **cell differentiation**. In our discussion of the genetic control of development in Chapter 17, you learned how cell differentiation occurs through **cell determination**, a series of molecular events in which the activities of certain genes are altered in ways that cause a cell to progressively commit to a particular differentiation pathway. This process proceeds even though there may not be any immediate changes in the cell's morphology. You also evaluated evidence supporting the principle of **nuclear equivalence**, which states that in most cases neither cell determination nor cell differentiation entails a loss of genetic information from the cell nucleus. That is, the nuclei of virtually all differentiated cells of an animal contain the same genetic information present in the zygote, but each cell type *expresses* a different subset of that information. In fact, nuclear equivalence is the principle that underlies the cloning of organisms.

Cell differentiation is therefore an expression of changes in the activity of specific genes, which in turn is influenced by a variety of factors inside and outside the cell. This **differential gene expression** is responsible for variations in chemistry, behavior, and structure among cells. Through this process, an embryo can develop into an organism of more than 200 types of cells, each specialized to perform specific functions. However, not all cells differentiate. Some, known as **stem cells**, remain in a relatively undifferentiated state and retain the ability to give rise to various cell types.

Cell differentiation by itself does not explain development. The differentiated cells must become progressively organized, shaping the intricate pattern of tissues and organs that characterizes a multicellular animal. This development of form, known as **morphogenesis**, proceeds through the process of pattern formation. **Pattern formation** is a series of steps requiring signaling between cells, changes in the shapes of certain cells, precise cell migrations, interactions with the extracellular matrix, and even **apoptosis** (programmed cell death; see Chapter 4) of some cells.

CHECKPOINT 51.1

- Which typically comes first, cell differentiation or cell determination?
- **CONNECT** What are some kinds of events that contribute to pattern formation? How does pattern formation lead to morphogenesis?

51.2 Fertilization

LEARNING OBJECTIVES

- 3 Describe the four processes involved in fertilization.
- 4 Describe fertilization in echinoderms and point out some ways in which mammalian fertilization differs.

In Chapter 50 you studied **spermatogenesis** and **oogenesis**, the processes by which meiosis leads to the formation of haploid cells, which differentiate as sperm and eggs, respectively. In **fertilization** a usually flagellated, motile sperm fuses with a much larger, immotile egg cell to produce a **zygote**, or fertilized egg.

Fertilization has two important genetic consequences: restoration of the diploid chromosome number and, in mammals and many other animals, determination of the sex of the offspring (see Chapter 11). Fertilization also has profound physiological effects because it activates the egg, thus initiating reactions that permit development.

Fertilization involves four events, some of which may occur simultaneously: (1) the sperm contacts the egg and recognition occurs; (2) the sperm or sperm nucleus enters the egg; (3) the egg becomes activated, and certain developmental changes begin; and (4) the sperm and egg nuclei fuse. These events do not necessarily follow the same temporal sequence in all animals. Unless otherwise stated, our discussion applies to sea urchins and other echinoderms such as sea stars, which have been studied intensively because they produce large numbers of gametes and because fertilization is external.

The first step in fertilization involves contact and recognition

Although eggs are immotile, they are active participants in fertilization. An egg is surrounded by a plasma membrane and by one or more external coverings that are important in fertilization. For example, a mammalian egg is enclosed by a thick, noncellular **zona pellucida**, which is surrounded by a layer of granulosa cells derived from the follicle in which the egg developed.

The egg coverings not only facilitate fertilization by sperm of the same species but also bar interspecific fertilization, a particularly important function in species that practice external fertilization. External to the plasma membrane of a sea urchin egg are two acellular layers that interact with sperm: a very thin **vitelline envelope** and, outside it, a thick glycoprotein layer called the **jelly coat**. Sea urchin sperm become motile when released into sea

water, and their motility increases when they reach the vicinity of a sea urchin egg. Motility improves the probability that sperm will encounter the egg, but motility alone may not be sufficient to ensure actual contact with the egg. In sea urchins as well as certain fishes and some cnidarians, the egg or one of its coverings secretes a chemotactic substance that attracts sperm from the same species. However, for many species, researchers have not found a specific chemical that attracts the sperm to the egg.

When a sea urchin sperm contacts the jelly coat, the sperm undergoes an **acrosome reaction**, in which the membranes surrounding the acrosome (the cap at the head of the sperm; see Fig. 50-6) fuse and pores in the membrane enlarge. Calcium ions from the sea water move into the acrosome, which swells and begins to disorganize. The acrosome then releases proteolytic enzymes that digest a path through the jelly coat to the vitelline envelope of the egg. If the sperm and egg are of the same species, *bindin*, a species-specific binding protein located on the acrosome, adheres to species-specific bindin receptors located on the egg's vitelline envelope.

Before a mammalian sperm participates in fertilization, it first undergoes **capacitation**, a maturation process in the female reproductive tract. During capacitation, which in humans can take several hours, sperm become increasingly motile and capable of undergoing an acrosome reaction when they encounter an egg. Evidence indicates that mammalian fertilization requires interaction between sperm and species-specific glycoproteins in the egg's zona pellucida.

Sperm entry is regulated

In sea urchins, once contact occurs between acrosome and vitelline envelope, enzymes dissolve a bit of the vitelline envelope in the area of the sperm head. The plasma membrane of the egg is covered with microvilli, several of which elongate to surround the head of the sperm. As they do so, the plasma membranes of sperm and egg fuse, and a *fertilization cone* is formed that contracts to draw the sperm into the egg (FIG. 51-1).

Fertilization of the egg by more than one sperm, a condition known as **polyspermy**, results in an offspring with extra sets of chromosomes, which is usually lethal. Two reactions, known as the fast and slow blocks to polyspermy, prevent this occurrence. In the *fast block to polyspermy*, the egg plasma membrane depolarizes, which prevents its fusion with additional sperm. An unfertilized egg is polarized; that is, the cytoplasm is negatively charged relative to the outside. However, within a few seconds after sperm fusion, ion channels in the plasma membrane open, permitting positively charged calcium ions to diffuse across the membrane and depolarize the egg.

The *slow block to polyspermy*, the **cortical reaction**, requires up to several minutes to complete, but it is a complete block. Binding of the sperm to receptors on the vitelline envelope activates one or more *signal transduction* pathways (see Chapter 6) in the egg. These events cause calcium ions stored in the egg endoplasmic reticulum to be released into the cytosol. This rise in the level of intracellular calcium causes thousands of cortical granules, membrane-enclosed vesicles in the egg cortex (region close to the plasma membrane), to release enzymes, various proteins, and other

Figure 51-1 Fertilization

In this TEM, a fertilization cone (FC) forms as a sperm enters a sea urchin egg. (SN, sperm nucleus; SM, sperm mitochondrion; SF, sperm flagellum).

substances by exocytosis into the space between the plasma membrane and the vitelline envelope (FIG. 51-2). Some of the enzymes dissolve the protein linking the two membranes; thus, the space enlarges as additional substances released by the cortical granules

Figure 51-2 The cortical reaction

Three cortical granules are undergoing exocytosis in this TEM of the plasma membrane of a sea urchin egg shortly after fertilization. This release of the contents of the cortical granules initiates the slow block to polyspermy.

raise the osmotic pressure, which causes an influx of water from the surroundings. The vitelline envelope then becomes elevated away from the plasma membrane and forms the fertilization envelope, a hardened covering that prevents entry of additional sperm.

In mammals, a fertilization envelope does not form. Instead, the enzymes released during exocytosis of the cortical granules alter the sperm receptors on the egg's zona pellucida so that no additional sperm bind to them.

Not all species have these types of blocks to polyspermy. In some species, such as salamanders, several sperm usually enter the egg, but only one sperm nucleus fuses with the egg nucleus; the rest degenerate.

Fertilization activates the egg

Release of calcium ions into the egg cytoplasm does more than stimulate the cortical reaction; it also triggers the *activation program*, a series of metabolic changes within the egg. Aerobic respiration increases; certain maternal enzymes and other proteins become active; and within a few minutes after sperm entry, a burst of protein synthesis occurs. In addition, the egg nucleus is stimulated to complete meiosis. (Recall from Chapter 50 that in most animal species, including mammals, at the time of fertilization an egg is actually a secondary oocyte, arrested early in the second meiotic division.)

In some species, an egg can be artificially activated without sperm penetration by swabbing it with blood and pricking the plasma membrane with a needle, by calcium injection, or by certain other treatments. These haploid eggs go through some developmental stages *parthenogenetically*—that is, without fertilization (see Chapter 50)—but they cannot complete development. Special mechanisms of egg activation have evolved in species that are naturally parthenogenetic.

Sperm and egg pronuclei fuse, restoring the diploid state

After the sperm nucleus enters the egg, researchers think that it is guided toward the egg nucleus by a system of microtubules that forms within the egg. The sperm nucleus swells and forms the *male pronucleus*. The nucleus formed during completion of meiosis in the egg becomes the *female pronucleus*. (Recall from Figure 50-11 that the other nucleus formed during meiosis II in the egg becomes the second polar body.) The haploid male and female pronuclei then fuse to form the diploid nucleus of the zygote, and DNA synthesis occurs in preparation for the first cell division.

CHECKPOINT 51.2

- How do the mechanisms of fertilization ensure control of both quality (fertilization by a sperm of the same species) and quantity (fertilization by only one sperm)?
- **CONNECT** What is the function of the cortical reaction in echinoderms? in mammals?

51.3 Cleavage

LEARNING OBJECTIVES

- 5 Trace the generalized pattern of early development of the embryo from zygote through early cleavage and formation of the morula and blastula.
- 6 Contrast early development, including cleavage, in the echinoderm (or in amphioxus), the amphibian, and the bird, paying particular attention to the importance of the amount and distribution of yolk.

Despite its simple appearance, the zygote is **totipotent**; that is, it gives rise to all the cell types of the new individual. Because the egg is very large compared with the sperm, the bulk of the zygote cytoplasm and organelles comes from the egg. However, the sperm and egg usually contribute equal numbers of chromosomes.

Shortly after fertilization, the zygote undergoes **cleavage**, a series of rapid mitotic divisions with no period of growth during each cell cycle. For this reason, although the cell number increases, the embryo does not increase in size. The zygote initially divides to form a 2-celled embryo. Then each of these cells undergoes mitosis and divides, bringing the number of cells to 4. Repeated divisions increase the number of cells, called **blastomeres**, that make up the embryo. At about the 32-cell stage, the embryo is a solid ball of blastomeres called a **morula**. Eventually, anywhere from 64 to several hundred blastomeres form the **blastula**, which is usually a hollow ball with a fluid-filled cavity, the **blastocoel**.

The pattern of cleavage is affected by yolk

Many animal eggs contain **yolk**, a mixture of proteins, phospholipids, and fats that serves as food for the developing embryo. The amount and distribution of yolk vary among different animal groups, depending on the needs of the embryo. Mammalian eggs have very little yolk because the embryo obtains maternal nutritional support throughout most of its development, whereas the eggs of birds and reptiles must contain sufficient yolk to sustain the embryo until hatching. Echinoderm eggs typically need only enough yolk to nourish the embryo until it becomes a tiny larva capable of obtaining its own food.

Most invertebrates and simple chordates have **isolecithal eggs** with relatively small amounts of yolk uniformly distributed through the cytoplasm. Isolecithal eggs divide completely in a process called **holoblastic cleavage**. Cleavage of these eggs is radial or spiral. Radial cleavage is characteristic of *deuterostomes*, such as chordates and echinoderms; spiral cleavage is common in the embryos of *protostomes*, such as annelids and mollusks (see Fig. 30-5).

In **radial cleavage**, the first division is vertical and splits the egg into two equal cells. The second cleavage division, also vertical, is at right angles to the first division and separates the two cells into four equal cells. The third division is horizontal, at right angles to the other two, and separates the four cells into eight cells: four above and four below the third line of cleavage.

Cleavage in sea stars is radial and holoblastic.

Figure 51-3
LMs showing sea star development

(a) The isolecithal egg has a small amount of uniformly distributed yolk. (b–e) The cleavage pattern is radial and holoblastic (the entire egg becomes partitioned into cells). (f, g) The three germ layers form during gastrulation. The blastopore is the opening into the developing gut cavity, the archenteron. The rudiments of organs are evident in the sea star larva (h) and the young sea star (i). All views are side views with the animal pole at the top except (c) and (i), which are top views. Note that the sea star larva is bilaterally symmetrical, but differential growth produces a radially symmetrical young sea star.

VISUALIZE Draw a simple sketch illustrating a horizontal section through the midplane of the middle gastrula in part (g). Label the archenteron and blastocoel. Is the blastopore included in your drawing?

This pattern of radial cleavage occurs in echinoderms and in the cephalochordate amphioxus (FIGS. 51-3 and 51-4).

In **spiral cleavage**, the plane of cytokinesis after the first two divisions is diagonal to the polar axis (FIG. 51-5). The result is a spiral arrangement of cells, with each cell located

above and between the two underlying cells. This pattern is typical of annelids and mollusks.

Many vertebrate eggs are **telolecithal**, meaning that they have large amounts of yolk concentrated at one end of the cell, known as the **vegetal pole**. The opposite, more metabolically

Key Point

Cleavage in amphioxus is radial and holoblastic.

Figure 51-4 Cleavage and gastrulation in amphioxus

As in the sea star, cleavage is holoblastic and radial. The embryos are shown from the side. **(a)** Mature egg with polar body. **(b–e)** The 2-, 4-, 8-, and 16-cell stages. **(f)** Embryo cut open to show the blastocoel. **(g)** Blastula. **(h)** Blastula cut open. **(i)** Early gastrula showing beginning of invagination at vegetal pole. **(j)** Late gastrula. Invagination is completed, and the blastopore has formed.

VISUALIZE Draw a simple sketch illustrating a horizontal section through the midplane of part **(j)**. Label the archenteron, endoderm, and ectoderm. Is the blastopore included in your drawing?

active pole is the **animal pole**. The eggs of amphibians are moderately telolecithal (mesolecithal). Although cleavage is radial and holoblastic, the divisions in the vegetal hemisphere are slowed by the presence of the inert yolk. As a result, the blastula consists of many small cells in the animal hemisphere and fewer but larger cells in the vegetal hemisphere (**FIG. 51-6**). The blastocoel is displaced toward the animal pole.

The telolecithal eggs of non-avian reptiles and birds have very large amounts of yolk at the vegetal pole and only a small amount of cytoplasm concentrated at the animal pole. The yolk of such eggs never cleaves. Cell division is restricted to the **blastodisc**, the small disc of cytoplasm at the animal pole (**FIG. 51-7**); this type of cleavage is called **meroblastic cleavage**. In birds and some reptiles, the blastomeres form two layers separated by the blastocoel cavity: an upper *epiblast* and a lower, thin layer of flat cells, the *hypoblast*.

Cleavage may distribute developmental determinants

The pattern of cleavage in a particular species depends on both yolk and other factors. Recall from Chapter 17 that some animals have relatively rigid developmental patterns, known as **mosaic development**. This type of development is largely a consequence of the unequal distribution of important materials in the cytoplasm of the zygote. Because the zygote cytoplasm is not homogeneous, cytoplasmic developmental determinants portioned out to each new cell during cleavage may be different. Such differences help determine the course of development. At the other extreme are mammals, which have zygotes with very homogeneous cytoplasm. They exhibit highly **regulative development**, in which individual cells produced by the cleavage divisions are equivalent, thus allowing the embryo to develop as a self-regulating whole. Developmental patterns of most animals fall somewhere on a continuum between these two extremes.

Key Point

Cleavage in annelids is spiral and holoblastic.

Figure 51-5 Spiral cleavage in an annelid embryo

(a–f) Top views of the animal pole. The successive cleavage divisions occur in a spiral pattern as illustrated. **(g)** A typical trochophore larva. The upper half of the trochophore develops into the extreme anterior end of the adult worm; all the rest of the adult body develops from the lower half.

VISUALIZE Draw a simple sketch illustrating how the embryo in part **(d)** (8-cell stage) would look if cleavage were radial rather than spiral.

Key Point

Cleavage in the moderately telolecithal frog egg is radial and holoblastic but is retarded by yolk in the vegetal hemisphere.

Figure 51-6 Cleavage pattern in a frog egg

(a–d) Although cleavage is holoblastic, the large amount of yolk concentrated in the vegetal hemisphere slows cleavage. As a result, fewer cells develop at the vegetal hemisphere than at the animal hemisphere. These embryos are shown from the side.

VISUALIZE Draw a simple sketch illustrating how the embryo in part (a) would look if the frog egg were isolecithal.

In some species the distribution of developmental determinants in the unfertilized egg is maintained in the zygote. In other species sperm penetration initiates rearrangement of the cytoplasm. For example, fertilization in the amphibian egg causes a shift of some of the cortical cytoplasm. These

(a) **Early blastodisc formation.** The blastodisc is a small disc of cytoplasm on the upper surface of the egg yolk. This cutaway view shows cells on the blastodisc surface as well as in the interior.

(b) **The blastodisc splits into two tissue layers, an upper epiblast and a lower hypoblast, separated by the blastocoel.**

Figure 51-7 Cleavage in a bird embryo

Cleavage in bird embryos is restricted to the blastodisc (meroblastic cleavage).

cytoplasmic movements can be easily followed because the egg cortex contains dark pigment granules. As a result of this rearrangement, a crescent-shaped region of underlying lighter colored (gray) cytoplasm becomes evident directly opposite the point on the cell where the sperm penetrated the egg. This **gray crescent** region is thought to contain growth factors and other developmental determinants. The first cleavage bisects the gray crescent, distributing half to each of the first two blastomeres; in this way the position of the gray crescent establishes the future right and left halves of the embryo. As cleavage continues, the gray crescent material becomes partitioned into certain blastomeres. Those that contain parts of the gray crescent eventually develop into the dorsal region of the embryo.

Experiments have confirmed the importance of determinants in the gray crescent to development. If the first two frog blastomeres are separated experimentally, each develops into a complete tadpole (FIG. 51-8a). When the plane of the first division is altered so that the gray crescent is completely absent from one of the cells, that cell does not develop normally (FIG. 51-8b).

Cleavage provides building blocks for development

Cleavage partitions the zygote into many small cells that serve as the basic building blocks for subsequent development. At the end of cleavage, the small cells that make up the blastula begin to move about with relative ease, arranging themselves into the patterns necessary for further development. Surface proteins are important in helping cells “recognize” one another and therefore in determining which ones adhere to form tissues.

CHECKPOINT 51.3

- **VISUALIZE** Draw simple sketches illustrating the difference between radial cleavage and spiral cleavage.
- What type of cleavage is characteristic of telolecithal eggs of reptiles and birds?
- **CONNECT** How do the amount and distribution of cytoplasm in the fertilized egg influence early development?

51.4 Gastrulation

LEARNING OBJECTIVE

- 7 Identify the significance of gastrulation in the developmental process and compare gastrulation in the echinoderm (or in amphioxus), the amphibian, and the bird.

The process by which the blastula becomes a three-layered embryo, or **gastrula**, is called **gastrulation**. Thus, early development proceeds through the following stages:

zygote → early cleavage stages → morula → blastula → gastrula

Key Experiment

Is the development of a frog egg influenced by cytoplasmic developmental determinants?

HYPOTHESIS: The gray crescent, which is normally bisected by the first cleavage division and thus establishes right and left halves of the embryo, is the location of crucial developmental determinants.

EXPERIMENT: The two blastomeres resulting from the first cleavage division are separated by the researcher and allowed to develop independently.

RESULTS AND CONCLUSION: Because only blastomeres containing all or part of the gray crescent developed into tadpoles, the gray crescent marks the location of essential developmental determinants in the fertilized egg.

SOURCE: H. Spemann, *Embryonic Development and Induction* (Yale University Press, New Haven, CT, 1938).

Figure 51-8 Cytoplasmic determinants in frog development

PREDICT Consider Gurdon's experiments demonstrating nuclear totipotency in frogs illustrated in Figure 17-3. What do you think would be the result if the same experiments were done, but substituting a blastomere lacking a gray crescent for an unfertilized egg?

During gastrulation, the embryo begins to approximate its body plan as cells arrange themselves into three distinct **germ layers**, or embryonic tissue layers: the outermost layer, the **ectoderm**; the innermost layer, the **endoderm**; and the **mesoderm**, which develops between them. Additional cell divisions take place during gastrulation, and the germ layers become established through a combination of processes. Many cells lose their old cell-to-cell contacts and establish new ones through cell recognition and adhesion processes involving interactions among the integrins and other plasma membrane proteins and the extracellular matrix (see Chapters 4 and 5). Many cells undergo cytoskeletal changes, particularly alterations in the distribution of actin microfilaments; these changes in the internal architecture of the cells allow them to change shape and/or undergo specific, directional, amoeboid movements. As a result of these movements, many cells ultimately take up new positions in the interior of the embryo.

Each of the germ layers develops into specific parts of the embryo. As you study the illustrations, keep in mind that a conventional color code accepted by developmental biologists is used to depict the germ layers: endoderm, yellow; mesoderm, red or pink; and ectoderm, blue.

The amount of yolk affects the pattern of gastrulation

The simple type of gastrulation that occurs in echinoderms and in amphioxus is illustrated in Figures 51-3f and g and 51-4i and j, respectively. Gastrulation begins when a group of cells at the vegetal pole undergoes a series of changes in shape that cause that part of the blastula wall to first flatten and then bend inward (invaginate). The invaginated wall eventually meets the opposite wall, obliterating the blastocoel.

You can roughly demonstrate this type of gastrulation by pushing inward on the wall of a partly deflated rubber ball until it rests against the opposite wall. In a similar way, the embryo is converted into a double-walled, cup-shaped structure. The new internal wall lines the **archenteron**, the newly formed cavity of the developing gut. The opening of the archenteron to the exterior, the **blastopore**, is the site of the future anus in deuterostomes.

This simple type of gastrulation cannot occur in the amphibian embryo because the large yolk-laden cells in the vegetal half of the blastula obstruct any inward movement at the vegetal pole. Instead, cells from the animal pole move down the embryo surface; when they reach the region derived from the gray crescent, they move into the interior. This inward movement is accomplished as the cells change shape, first becoming flask- or bottle-shaped (so that most of their mass is actually below the surface) and then sinking into the interior as they lose their remaining connections with other cells on the surface. This spot on the embryo's surface, referred to as the **dorsal lip of the blastopore**, is marked by a dimple, shaped like a C lying on its side (**FIG. 51-9**). As the process continues, the blastopore becomes ring-shaped as cells lateral, and then ventral, to its dorsal lip become involved in similar

Gastrulation forms the three germ layers: endoderm, ectoderm, and mesoderm.

Figure 51-9 Gastrulation in a frog embryo

The embryos in the diagrams are cut in half longitudinally to show the formation of the germ layers.

CONNECT What does the archenteron become in the tadpole? the blastopore? the blastocoel?

movements. The yolk-filled cells fill the space enclosed by the lips of the blastopore, forming the yolk plug.

The archenteron forms and is lined on all sides by cells that have moved in from the surface. At first, the archenteron is a narrow slit, but it gradually expands at the anterior end of the embryo. As a result, the blastocoel progressively shrinks and eventually disappears.

Although the details differ somewhat, gastrulation in birds is basically similar to amphibian gastrulation. Cells that make up the upper layer (the epiblast) migrate toward the midline to form a thickened region known as the **primitive streak**, which elongates and narrows as it develops. At its center is a narrow furrow, the **primitive groove**. The primitive streak is a dynamic structure. Its cells constantly change as they migrate in from the epiblast, sink inward at the primitive groove, and then move out laterally and anteriorly in the interior (FIG. 51-10). The primitive groove is the functional equivalent of the blastopore of the echinoderm, amphioxus, and amphibian embryos. However, a bird embryo contains no cavity homologous to the archenteron.

At the anterior end of the primitive streak, cells destined to form the **notochord** (supporting rod of mesodermal cartilage-like cells that serves as the flexible skeletal axis in all chordate embryos) concentrate in a thickened knot known as **Hensen's node**. These cells sink into the interior and then move anteriorly just beneath the epiblast, forming a narrow extension from the node. Cells that will form other types of mesoderm move laterally and anteriorly from the primitive

streak, between the epiblast (which becomes ectoderm) and the hypoblast. Other cells that form the endoderm displace the hypoblast cells and cause them to move laterally. These displaced cells will form part of the extraembryonic membranes, discussed in a later section.

Figure 51-10 Gastrulation in birds

A three-layered embryo forms as cells move toward the primitive streak, move inward at the primitive groove, and migrate laterally and anteriorly in the interior. The red cells will develop as mesoderm. Cells shown just above the double-headed arrow have migrated into the hypoblast; they are moving laterally and will eventually become endoderm.

- **CONNECT** What is the archenteron? Is an archenteron formed in sea stars? in amphibians? in birds?
- **CONNECT** How do the amount and distribution of yolk influence gastrulation?

51.5 Organogenesis

LEARNING OBJECTIVES

- 8 Define *organogenesis* and summarize the fate of each of the germ layers.
- 9 Trace the early development of the vertebrate nervous system.

Gastrulation leads to **organogenesis**, or organ formation, in which the cells of the three germ layers continue the processes of pattern formation that lead to the formation of specific structures. The ectoderm eventually forms the outer layer of the skin and gives rise to the nervous system and sense organs. Tissues that eventually line the digestive tract, and organs that develop as outgrowths of the digestive tract (including the liver, pancreas, and lungs), are all of endodermal origin. Skeletal tissue, muscle, and the circulatory, excretory, and reproductive systems all are derived from mesoderm (TABLE 51-1; see Fig. 17-1).

The notochord, brain, and spinal cord are among the first organs to develop in the early vertebrate embryo (FIG. 51-11; see also Figs. 51-9d and e). First, the notochord, which is mesodermal tissue, grows forward along the length of the embryo as a cylindrical rod of cells. The notochord is eventually replaced by the vertebral column, although notochord remnants will remain in the cartilage discs between the vertebrae.

Table 51-1 Fate of the Germ Layers Formed at Gastrulation

ECTODERM

Nervous system and sense organs
Outer layer of skin (epidermis) and its associated structures (nails, hair, etc.)
Pituitary gland

MESODERM

Notochord

Circulatory system
Excretory system
Reproductive system
Inner layer of skin (dermis)
Outer layers of digestive tube and of structures that develop from it, such as part of the respiratory system

ENDODERM

Lining of digestive tube and of structures that develop from it, such as lining of the respiratory system

The developing notochord has yet another crucial function. Numerous experiments in which researchers have transplanted portions of the notochord mesoderm to other locations in the embryo show that the notochord causes the overlying ectoderm to thicken and differentiate to form the precursor of the central nervous system, the **neural plate**. Such phenomena, in which certain cells stimulate or otherwise influence the differentiation of their neighbors, are examples of **induction** (see Chapter 17).

Repeated testing supports the hypothesis that induction of the neural plate cells does not require direct cell-to-cell contact with the developing notochord cells. Researchers therefore think that this induction involves the diffusion of some type of signal molecule, although they have not yet identified the chemical signal itself. The induction of the neural plate by the notochord is a good example of the importance of a cell's position in relation to other cells. That position is often

(a) Approximately 19 days. The neural plate has begun to indent and form a shallow groove that will be flanked by neural folds.

(b) Approximately 20 days. The neural folds approach one another. The neural crest cells, derived from ectoderm, will migrate in the embryo and give rise to sensory neurons; the somites are blocks of mesoderm that become the vertebrae and other segmented body parts. (The endoderm is not shown.)

(c) Approximately 26 days. The neural folds have joined to form the hollow neural tube, which gives rise to the brain at the anterior end of the embryo and the spinal cord posteriorly. (The endoderm is not shown.)

Figure 51-11 Development of the human nervous system

critical in determining the fate of a cell because it determines the cell's exposure to substances released from other cells.

The cells of the neural plate undergo changes in shape that cause the central cells of the neural plate to move downward and form a depression called the *neural groove*; the cells flanking the groove on each side form *neural folds*. Continued changes in cell shape bring the folds closer together until they meet and fuse to form the **neural tube**. In this process, the hollow neural tube comes to lie beneath the surface. The ectoderm overlying it will form the outer layer of skin. The anterior portion of the neural tube grows and differentiates into the brain; the rest of the tube develops into the spinal cord. The brain and the spinal cord remain hollow, even in the adult; the ventricles of the brain and central canal of the spinal cord are persistent reminders of their embryonic origins.

Various motor nerves grow out of the developing brain and spinal cord, but sensory nerves have a separate origin. When the neural folds fuse to form the neural tube, bits of nervous tissue known as the *neural crest* arise from ectoderm on each side of the tube. **Neural crest cells** migrate downward from their original position and form the dorsal root ganglia of the spinal nerves and the postganglionic sympathetic neurons. From sensory cells in the dorsal root ganglia, dendrites grow out to the sense organs, and axons grow into the spinal cord. Other neural crest cells migrate to various locations in the embryo. They give rise to parts of certain sense organs, nearly all pigment-forming cells in the body, and parts of the head. Some head derivatives of the neural crest are the cartilage and bone of the skull, face, and jaw; connective tissue in the eye and face dermis; sensory nerves and other parts of the peripheral nervous system; and ganglia of the autonomic nervous system.

As the nervous system develops, other organs also begin to take shape. Blocks of mesoderm known as somites form on either side of the neural tube and will give rise to the vertebrae, muscles, and other components of the body axis. In addition to the skeleton and muscles, mesodermal structures include the kidneys, reproductive structures, and the circulatory organs. In fact, the heart and blood vessels are among the first structures to form, and they must function while still developing.

The development of the four-chambered heart of birds and mammals is a good example of organogenesis (FIG. 51-12; see Chapter 44). The heart originates through the fusion of paired blood vessels. Venous blood enters the single atrium; passes into the single ventricle, which is located above the atrium; and is then pumped into the embryo. During subsequent development, the atrium undergoes a process of torsion that brings it to a position above the ventricle, and partitions form that divide the atrium and the ventricle into right and left chambers.

The digestive tract is first formed as a separate foregut and hindgut as the body wall grows and folds; this process cuts them off as two simple tubes. As the embryo grows, these tubes, which are lined with endoderm, grow and become greatly elongated. The liver, pancreas, and trachea originate as hollow, tubular outgrowths from the gut. As the trachea grows downward, it gives rise to the paired lung buds, which develop into lungs. The most anterior part of the foregut becomes the pharynx.

Figure 51-12 Formation of the heart in birds and mammals

These ventral views of successive stages show that the heart forms from the fusion of two blood vessels and that at first the end that receives blood from the veins is at the bottom. The developing heart twists to carry the atrium to a position above the ventricle, and the chambers then divide to form the four-chambered heart.

A series of small outpocketings of the pharynx, the *pharyngeal pouches*, bud out laterally. These pouches meet the *branchial grooves*, a corresponding set of inpocketings from the overlying ectoderm. The arches of tissue formed between the grooves are called *branchial arches*. They contain the rudimentary skeletal, neural, and vascular elements of the face, jaws, and neck.

In fishes and some amphibians, the pharyngeal pouches and branchial grooves meet and form a continuous passage from the pharynx to the outside; these gill slits function as respiratory organs. In terrestrial vertebrates, each branchial groove remains separated from the corresponding pharyngeal pouch by a thin membrane of tissue, and these structures give rise to organs more appropriate for life on land. For example, the middle-ear cavity and its connection to the pharynx, the eustachian tube, derive from a pharyngeal pouch.

CHECKPOINT 51.5

- **CONNECT** What adult structures develop from each germ layer?
- **CONNECT** How do cell division, growth, cell differentiation, and morphogenesis interact in the formation of the neural tube?
- What is the developmental significance of the neural crest cells?

51.6 Extraembryonic Membranes

LEARNING OBJECTIVE

- 10** Give the origins and functions of the chorion, amnion, allantois, and yolk sac.

In terrestrial vertebrates, the three germ layers also give rise to four **extraembryonic membranes**: the chorion, amnion, allantois, and yolk sac (FIG. 51-13). Although they develop from the germ layers, these membranes are not part of the embryo itself and are discarded at hatching or birth. The extraembryonic membranes are adaptations to the challenges of embryonic development on land. They protect the embryo, prevent it from drying out, and help in obtaining food and oxygen and eliminating wastes.

The outermost membrane, the **chorion**, encloses the entire embryo as well as the other membranes. Lying underneath the eggshell in birds and reptiles, it functions as the major organ of gas exchange. As you will see in the next section, its functions have been extended in humans and most other mammals.

Like the chorion, the **amnion** encloses the entire embryo. The amniotic cavity, the space between the embryo and the amnion, becomes filled with amniotic fluid secreted by the membrane. (Recall from Chapter 32 that terrestrial vertebrates are known

as *amniotes* because their embryos develop within this pool of fluid.) The amniotic fluid prevents the embryo from drying out and permits it a certain freedom of motion. The fluid also serves as a protective cushion that absorbs shocks and prevents the amniotic membrane from sticking to the embryo. In current medical practice, a sample of amniotic fluid can be obtained through a procedure known as *amniocentesis* and analyzed for biochemical or chromosomal abnormalities that indicate a possible birth defect (see Fig. 16-12).

The **allantois** is an outgrowth of the developing digestive tract. In reptiles and birds, it stores nitrogenous wastes. In humans, the allantois is small and nonfunctional except that its blood vessels contribute to the formation of umbilical vessels joining the embryo to the placenta. In vertebrates with yolk-rich eggs, the **yolk sac** encloses the yolk, slowly digests it, and makes it available to the embryo. A yolk sac, connected to the embryo by a yolk stalk, develops even in mammalian embryos that have little or no yolk. Its walls serve as temporary centers for the formation of blood cells.

CHECKPOINT 51.6

- What are the roles of the chorion and amnion in terrestrial vertebrate embryos?
- CONNECT** What are the functions of the allantois and yolk sac in birds? Do they have comparable roles in mammals? Explain your answer.

Figure 51-13 Extraembryonic membranes

The formation of the extraembryonic membranes of the chick is illustrated at (a) four days, (b) five days, and (c) nine days of development. Each of the membranes develops from a combination of two germ layers. The chorion and amnion form from lateral folds of the ectoderm and mesoderm that extend over the embryo and fuse. The allantois and the yolk sac develop from endoderm and mesoderm.

51.7 Human Development

LEARNING OBJECTIVES

- 11** Describe the general course of early human development, including fertilization, the fates of the trophoblast and inner cell mass, implantation, and the role of the placenta.
- 12** Contrast postnatal and prenatal life, describing several changes that occur at or shortly after birth that allow the neonate to live independently.

The human *gestation period*, the duration of pregnancy, averages 266 days (38 weeks, or about 9 months) from the time of fertilization to the birth of the baby (TABLE 51-2). We will use this system of timing when discussing the events of early development. Because the time of fertilization is not easily marked, obstetricians usually time the pregnancy by counting from the date of onset of the woman's last menstrual period; by this calculation, an average pregnancy is 280 days (40 weeks).

Fertilization occurs in the oviduct, and within 24 hours the human zygote has divided to become a 2-celled embryo (FIG. 51-14). Cleavage continues as the embryo is propelled along the oviduct by ciliary action.

When the embryo enters the uterus on about the fifth day of development, the *zona pellucida* (its surrounding coat) is dissolved. During the next few days, the embryo floats free in the uterine cavity and is nourished by a nutritive fluid secreted

Table 51-2 Some Important Developmental Events in the Human Embryo

Time from Fertilization	Event
24 hours	Embryo reaches 2-cell stage
3 days	Morula reaches uterus
7 days	Blastocyst begins to implant
2.5 weeks	Notochord and neural plate are formed; tissue that will give rise to heart is differentiating; blood cells are forming in yolk sac and chorion
3.5 weeks	Neural tube forming; primordial eye and ear visible; pharyngeal pouches forming; liver bud differentiating; respiratory system and thyroid gland just beginning to develop; heart tubes fuse, bend, and begin to beat; blood vessels are laid down
4 weeks	Limb buds appear; three primary divisions of brain forming
2 months	Muscles differentiating; embryo capable of movement; gonad distinguishable as testis or ovary; bones begin to ossify; cerebral cortex differentiating; principal blood vessels assume final positions
3 months	Sex can be determined by external inspection; notochord degenerates; lymph glands develop
4 months	Face begins to look human; lobes of cerebrum differentiate; eyes, ears, and nose look more "normal"
Third trimester	Downy hair covers the fetus, then later is shed; neuron myelination begins; tremendous growth of body
266 days	Birth

by the glands of the uterus. Its cells arrange themselves, forming a blastula, which in mammals is called a **blastocyst**. The outer layer of cells, the **trophoblast**, eventually forms the chorion and amnion that surround the embryo. A little cluster of cells, the **inner cell mass**, projects into the cavity of the blastocyst. The inner cell mass gives rise to the embryo proper.

On about the seventh day of development, the embryo begins the process of **implantation**, in which it embeds in the endometrium of the uterus (FIG. 51-15). The trophoblast cells in contact with the endometrium secrete enzymes that erode an area just large enough to accommodate the tiny embryo. As the embryo slowly works its way into the underlying connective and vascular tissues, the opening in the endometrium repairs itself. All further development of the embryo takes place *within* the endometrium.

The placenta is an organ of exchange

In placental mammals, the **placenta** is the organ of exchange between mother and embryo (see Fig. 51-15). The placenta provides nutrients and oxygen for the fetus and removes wastes, which the mother then excretes. In addition, the placenta is an endocrine organ that secretes estrogens and progesterone to maintain pregnancy. The placenta develops from both the chorion of the embryo and the uterine tissue of the mother. In early development, the chorion grows rapidly, invading the endometrium and forming fingerlike projections known as *chorionic villi*. The chorionic villus sampling technique allows prenatal detection of certain genetic disorders (see Fig. 16-13). The villi become vascularized (infiltrated with blood vessels) as the embryonic circulation develops.

Figure 51-14 Cleavage in a human embryo

As the human embryo grows, the **umbilical cord** develops and connects the embryo to the placenta (see Fig. 51-15e). The umbilical cord contains the two umbilical arteries and the umbilical vein. The umbilical arteries connect the embryo to a vast network of capillaries developing within the chorionic villi. Blood from the villi returns to the embryo through the umbilical vein.

The placenta consists of the portion of the chorion that develops villi, together with the underlying uterine tissue that contains maternal capillaries and small pools of maternal blood. The fetal blood in the capillaries of the chorionic villi comes in close contact with the mother's blood in the tissues between the villi. The two circulations are always separated by a membrane through which substances may diffuse or be actively transported. Maternal and fetal blood do not normally mix in the placenta or any other place.

The placenta produces several hormones. From the time the embryo first begins to implant itself, its trophoblastic cells release **human chorionic gonadotropin (hCG)**, which signals the corpus luteum (see Chapter 50) that pregnancy has begun. In response, the corpus luteum increases in size and releases large amounts of progesterone and estrogens. These hormones stimulate continued development of the endometrium and placenta.

Without hCG, the corpus luteum would degenerate and the embryo would abort and be flushed out with the menstrual flow. The woman would probably not even know she had been pregnant. If the corpus luteum is removed before about the 11th week after fertilization, the embryo spontaneously aborts. After that time, the placenta itself produces enough progesterone and estrogens to maintain pregnancy.

Figure 51-15 Implantation and early development in the uterus

Organ development begins during the first trimester

Gastrulation occurs during the second and third weeks of development. Then the notochord begins to form and induces formation of the neural plate. The neural tube develops, and the forebrain, midbrain, and hindbrain are evident by the fifth week of development. A week or so later, the forebrain begins to grow outward, forming the rudiments of the cerebral hemispheres.

The heart begins to develop and after 3.5 weeks begins to beat spontaneously because the embryo is growing large enough to require a functional circulatory system. Pharyngeal pouches, branchial grooves, and branchial arches form in the region of the developing pharynx. In the floor of the pharynx, a tube of cells grows downward to form the primordial trachea, which gives rise to the lung buds. The digestive system also gives rise to outgrowths that develop into the liver, gallbladder, and pancreas. A thin tail becomes evident but does not grow as rapidly as the rest of the body and so becomes inconspicuous by the end of the second month. Near the end of the fourth week, the limb buds begin to differentiate; they eventually give rise to arms and legs.

The reproductive system begins development during the fourth week. Paired gonads form, but they are undifferentiated and not distinguishable as ovaries or testes. As shown in **FIGURE 51-16**, two pairs of potential systems of reproductive ducts form, the *Wolffian ducts* and the *Müllerian ducts*, as well as the *genital tubercle*, a small precursor of the penis or clitoris. If the embryo is XY, as discussed in Chapter 11, the *SRY* (*sex reversal on Y*) gene becomes activated, causing the gonads to

Figure 51-16 The human reproductive system in its early, undifferentiated state

If the embryo is XY, the gonads will develop as testes, the Wolffian ducts will become the vasa deferentia and associated structures, and the Müllerian ducts will degenerate. In an XX embryo, the gonads develop as ovaries, the Müllerian ducts become the oviducts and associated structures, and the Wolffian ducts degenerate.

develop as testes. The testes produce testosterone and other hormones that cause the Wolffian ducts to develop into the vasa deferentia and associated internal structures of the male and the genital tubercle to develop as a penis. The Müllerian ducts degenerate. If the embryo is XX, the gonads differentiate as ovaries, the Wolffian ducts degenerate, the Müllerian ducts develop into the oviducts and associated internal structures, and the genital tubercle develops as the clitoris.

All the organs continue to develop during the second month (see chapter-opening photograph). Muscles develop, and the embryo becomes capable of movement. The brain begins to send impulses that regulate the functions of some organs, and a few simple reflexes are evident. After the first two months of development, the embryo is referred to as a **fetus** (**FIG. 51-17**).

By the end of the *first trimester* (the first three months of development), the fetus is about 56 mm (2.2 in.) long and weighs about 14 g (0.5 oz). Although small, it looks human. The external genital structures have differentiated, indicating the sex of the fetus. Ears and eyes approach their final positions. Some of the skeleton becomes distinct, and the developing vertebral column has replaced the notochord. The fetus performs breathing movements, pumping amniotic fluid into and out of its lungs, and even makes sucking motions.

Development continues during the second and third trimesters

During the second trimester (months four through six), the fetal heart can be heard with a stethoscope. The fetus moves freely within the amniotic cavity, and during the fifth month the mother usually becomes aware of relatively weak fetal movements (“quickening”). The fetus grows rapidly during the final trimester (months seven through nine), and final

Figure 51-17 Human fetus at 10 weeks

Note the position of the fetus within the uterine wall.

differentiation of tissues and organs occurs. If born at 24 weeks (out of 40 weeks), the fetus has only about a 50% chance of surviving, even with the best of medical care. Its brain is not yet sufficiently developed to sustain vital functions such as rhythmic breathing, and the kidneys and lungs are immature.

During the seventh month, the cerebrum grows rapidly and develops convolutions. The grasping and sucking reflexes are evident, and the fetus may suck its thumb. Any infant born before 37 weeks (out of 40) is considered premature. According to statistics made available by the March of Dimes, premature birth is an increasing problem in the United States, its incidence having risen to 9.6% in 2016. Each year, well over half a million premature babies are born in the United States and more than 15 million worldwide. Babies born at 28 or fewer weeks are at greatest risk of death and severe defects. Babies born closer to 37 weeks have a greater chance of survival with competent medical care but may still face multiple long-term health problems.

At birth the average full-term baby in the United States weighs about 3400 g (7.5 lb) and measures about 52 cm (20 in.) in total length. A baby that weighs less than 2500 g (5.5 lb) is considered low birth weight and is at risk even if not premature.

More than one mechanism can lead to a multiple birth

Occasionally, the cells of the 2-cell embryo separate, and each cell develops into a complete organism. Alternatively, sometimes the inner cell mass subdivides, forming two groups of cells, each of which develops independently. Because these cells have identical sets of genes, the individuals formed are exactly alike and are called **monozygotic**, or identical, twins. Very rarely, the two inner cell masses do not completely separate and so give rise to *conjoined twins*, who are physically attached and usually share one or more body parts.

Dizygotic twins, also called fraternal twins, develop when two eggs are ovulated and each is fertilized by a different sperm. Each zygote has its own distinctive genetic endowment, so the individuals produced are not identical. They may not even be of the same sex. Similarly, triplets (and other multiple births) may be either identical or fraternal.

Before fertility-inducing agents became available in the United States, about 2.5% of babies born were twins, and higher multiples were very rare. However, widespread use of drugs to improve fertility has been linked to an increase in multiple births. The March of Dimes reports that between 1980 and 2004 the rate of twin births increased by about 70% and the rate of triplet births increased fivefold. These rates may now be stabilizing; the rate of twin births does not appear to be increasing, and the rate of triplet births has declined slightly.

A family history of twinning increases the probability of having dizygotic twins. However, giving birth to monozygotic twins is probably not influenced by heredity, age of the mother, or other known factors. An estimated two-thirds of multiple pregnancies end in the birth of a single baby; the other embryo(s) may be absorbed within the first ten weeks of pregnancy, or spontaneously aborted. Ultrasound imaging techniques are used to produce a type of image known as a **sonogram**, which can provide

valuable data regarding the presence of multiple embryos. This information is medically important because multiple births are associated with higher infant mortality, which is largely a consequence of an increased risk of prematurity and low birth weight.

Environmental factors affect the embryo

We all know that the growth and development of babies are influenced by the food they eat, the air they breathe, the disease organisms that infect them, and the chemicals or drugs to which they are exposed. **Prenatal** development is also affected by these environmental influences. Life before birth is even more sensitive to environmental changes than it is for the fully formed baby. Although there is no direct mixing of maternal and fetal blood, diffusion and various other mechanisms allow many substances—nutrients, drugs, pathogens, and gases—to travel across the placenta.

TABLE 51-3 describes some environmental influences on development. Some of them are **teratogens**, drugs or other substances that interfere with morphogenesis and so cause malformations. Many factors, such as smoking, alcohol use, and poor nutrition, contribute to low birth weight, a condition responsible for many infant deaths.

About one out of every 33 newborns in the United States has a defect of clinical significance. Such birth defects account for more than 20% of deaths among newborns. Birth defects may be caused by genetic and/or environmental factors. Genetic factors were discussed in Chapter 17. In this section we examine some environmental conditions that affect the well-being of the embryo.

Timing is important. Each developing structure has a critical period during which it is most susceptible to unfavorable conditions. Generally, this critical period occurs early in the structure's development, when interference with cell movements or divisions may prevent formation of normal shape or size, resulting in permanent malformation. Because most structures form during the first three months of embryonic life, the embryo is most susceptible to environmental factors during this early period. During part of this time, the woman may not even realize that she is pregnant and so may not take special precautions to minimize potential dangers.

Physicians diagnose some defects while the embryo is in the uterus. In some cases, treatment is possible before birth. Amniocentesis and chorionic villus sampling, discussed in Chapter 16, are techniques used to detect certain defects. Ultrasound imaging techniques mentioned previously help diagnose defects and determine the position of the fetus. Ultrasound has been used for many years, and unlike imaging techniques that use radiation, no risk of harm to the fetus has been traced to its use. New methods currently under development or refinement include special types of magnetic resonance imaging, or MRI, and high-resolution, three-dimensional ultrasound imaging (**FIG. 51-18**).

The neonate must adapt to its new environment

Important changes take place after birth. During prenatal life, the fetus received both food and oxygen from the mother through the placenta. Now the newborn's own digestive and

Table 51-3 Environmental Influences on the Embryo

Factor	Example and Effect	Comment
NUTRITION	Severe protein malnutrition doubles number of defects, fewer brain cells are produced, and learning ability may be permanently affected; deficiency of folic acid (a vitamin) linked to CNS defects such as spina bifida (open spine), low birth weight.	Growth rate mainly determined by rate of net protein synthesis by embryo's cells.
MEDICATIONS	Many medications, even aspirin, affect development of the fetus.	Herbal drugs and dietary supplements are unregulated.
Excessive vitamins	Vitamin D essential, but excessive amounts may result in a form of intellectual disability; an excess of vitamins A and K may also be harmful.	Vitamin supplements are normally prescribed for pregnant women, but only the recommended dosage should be taken.
Thalidomide	Thalidomide, marketed in Europe as a mild sedative, was responsible for serious malformations in about 10,000 babies born in the late 1950s in 20 countries; principal defect was phocomelia, a condition in which babies are born with extremely short limbs, often with no fingers or toes.	This teratogenic drug interferes with the development of blood vessels and nerves; most hazardous when taken during fourth to fifth weeks, when limbs are developing; thalidomide has been approved for the treatment of leprosy and certain cancers (e.g., myeloma), and clinical trials are being conducted to test its usefulness in the treatment of other cancers and some of the complications of AIDS.*
Accutane (isotretinoin)	Accutane, a synthetic derivative of vitamin A, is used for the treatment of cystic acne. A woman who takes Accutane during pregnancy has a one in five chance of having a child with serious malformations of the brain (causing intellectual disability), head and face, thymus gland (interfering with immune function), or heart.	Although Accutane is marketed with severe restrictions to prevent pregnant women from taking this teratogenic drug, several children are born each year with birth defects attributable to Accutane exposure.
PATHOGENS		
Zika	Zika virus is carried by mosquitos and is also transmitted sexually.	One study found that fetal infection with Zika virus caused a variety of birth defects in at least 10% of cases; these included microcephaly (smaller than usual head size), brain damage and other neurological abnormalities, and limb defects. As of 2017, there was no vaccine and no treatment.
Rubella	Rubella (German measles) virus crosses placenta and infects embryo; interferes with normal metabolism and cell movements; causes syndrome that involves blinding cataracts, deafness, heart malformations, and intellectual disability; risk is greatest (about 50%) when rubella is contracted during the first month of pregnancy; risk declines with each succeeding month.	Rubella epidemic in the United States in 1963–1965 resulted in about 20,000 fetal deaths and 30,000 infants born with serious defects; immunization is available but must be administered several months before conception.
HIV*	HIV can be transmitted from mother to baby before birth.	See discussion of AIDS in Chapter 45.
Syphilis	Syphilis is transmitted to fetus in about 40% of infected women; fetus may die or be born with defects and congenital syphilis.	Pregnant women are routinely tested for syphilis during prenatal examinations; most cases can be safely treated with antibiotics.
IONIZING RADIATION	When a pregnant woman is subjected to X-rays or other forms of radiation, infant has a higher risk of birth defects and leukemia.	Radiation was one of the earliest causes of birth defects to be recognized.
RECREATIONAL AND/OR ABUSED SUBSTANCES		
Alcohol	When a woman drinks heavily during pregnancy, the baby may be born with fetal alcohol syndrome (FAS), which includes certain physical deformities and intellectual disability; low birth weight and structural abnormalities have been associated with as little as two drinks a day; some cases of hyperactivity and learning disabilities have occurred.	FAS is the leading cause of preventable intellectual disability in the United States.
Cigarette smoking	Cigarette smoking reduces the amount of oxygen available to the fetus because some of the maternal hemoglobin is combined with carbon monoxide; may slow growth and can cause subtle forms of damage.	Mothers who smoke cigarettes deliver babies with lower-than-average birth weights and have a higher incidence of spontaneous abortions, stillbirths, and neonatal deaths, especially from SIDS;* studies also indicate a possible relationship between maternal smoking and slower intellectual development in offspring.
Cocaine	Constricts fetal arteries, resulting in retarded development and low birth weight; in severe cases there may be learning and behavioral problems, heart defects, and other medical problems.	Cocaine users frequently abuse alcohol as well, so it is difficult to separate the effects.
Heroin	High rates of mortality and prematurity; low birth weight.	Infants who survive are born addicted and must be treated for weeks or months; risk of SIDS is increased ten-fold.

* AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus; SIDS, sudden infant death syndrome

Figure 51-18 Three-dimensional ultrasound image of a human fetus at about 16 weeks gestation
Note the enhanced soft tissue detail.

respiratory systems must function. Correlated with these changes are several major changes in the circulatory system.

Normally, the **neonate** (newborn infant) begins to breathe within a few seconds of birth and cries within half a minute. If anesthetics have been given to the mother, however, the fetus may also be anesthetized, and its breathing and other activities may be depressed. Some infants may not begin breathing immediately, which is one reason many women request child-birth methods that minimize the use of medication.

Researchers think that the neonate's first breath is initiated by the accumulation of carbon dioxide in the blood after the umbilical cord is cut. Carbon dioxide stimulates the respiratory centers in the medulla. The resulting expansion of the lungs enlarges its blood vessels (which in the uterus were

partially collapsed). Blood from the right ventricle flows in increasing amounts through these larger pulmonary vessels. (During fetal life, blood bypasses the lungs in two ways: by flowing through an opening, the *foramen ovale*, which shunts blood from the right atrium to the left atrium; and by flowing through an arterial duct connecting the pulmonary artery and aorta. Both of these routes close off after birth.)

Aging is not a uniform process

We have examined briefly the development of the embryo and fetus, the birth process, and the adjustments required of the neonate. The human life cycle then proceeds through the stages of infant, child, adolescent, young adult, middle-aged adult, and elderly adult.

Development encompasses any biological change within an organism over time, including the changes commonly called **aging**. Changes during the aging process decrease function in the older individual. The declining capacities of the various systems in the human body, although most apparent in the elderly, may begin much earlier in life. Relatively little is known about the aging process itself; it is now an active field of investigation, and researchers are gaining considerable insight through genetic studies on model organisms such as the nematode worm, *Caenorhabditis elegans*; the fruit fly, *Drosophila melanogaster*; and the laboratory mouse, *Mus musculus* (see Chapter 17).

CHECKPOINT 51.7

- How does a human blastocyst form and implant?
- How does the placenta form, and what is its function?
- During which trimester does the cerebrum develop convolutions? When do the limb buds begin to differentiate?
- **CONNECT** What differences between fetal life and the life of a neonate require adaptations immediately after birth?

Summary: Focus on Learning Objectives

51.1 Development of Form (page 1105)

- 1 **Analyze the relationship between cell determination and cell differentiation and between pattern formation and morphogenesis.**
 - **Cell determination** is a series of molecular events that lead to **cell differentiation**, in which a cell becomes specialized and carries out specific functions. Relatively undifferentiated cells are known as **stem cells**.
 - **Morphogenesis**, the development of form, occurs through **pattern formation**, a series of events in which cells may communicate by signaling, migrate, undergo changes in shape, and even undergo **apoptosis** (programmed cell death).

2 Relate differential gene expression to nuclear equivalence.

- Usually no genetic changes occur in cell determination and cell differentiation (the principle of **nuclear equivalence**). Instead, various types of differentiated cells express different subsets of their genes (**differential gene expression**).

51.2 Fertilization (page 1105)

3 Describe the four processes involved in fertilization.

- Contact and recognition occur between noncellular egg coverings and sperm.
- Sperm entry is regulated to prevent interspecific fertilization and **polyspermy**, which is fertilization of the egg by more than one sperm.

- Fertilization activates the egg, triggering the events of early development.
- Sperm and egg pronuclei fuse and initiate DNA synthesis.

4 Describe fertilization in echinoderms and point out some ways in which mammalian fertilization differs.

- The coverings of echinoderm eggs are the **vitelline envelope** and the **jelly coat**; a **zona pellucida** encloses the mammalian egg.
- On contact, a sperm undergoes an **acrosome reaction**, which facilitates penetration of the egg coverings; in mammals the acrosome reaction is preceded by **capacitation**, a maturation process that results in the ability of a sperm to fertilize an egg.
- Sea urchin fertilization is followed by a fast block to polyspermy (depolarization of the plasma membrane) and a slow block to polyspermy (the **cortical reaction**); changes in the zona pellucida prevent polyspermy in mammals.

51.3 Cleavage (page 1107)

5 Trace the generalized pattern of early development of the embryo from zygote through early cleavage and formation of the morula and blastula.

- The zygote undergoes **cleavage**, a series of rapid cell divisions without a growth phase. The main effect of cleavage is to partition the zygote into many small **blastomeres**.
- Cleavage forms a solid ball of cells called the **morula** and then usually a hollow ball of cells called the **blastula**.

6 Contrast early development, including cleavage, in the echinoderm (or in amphioxus), the amphibian, and the bird, paying particular attention to the importance of the amount and distribution of yolk.

- The **isolecithal eggs** of most invertebrates and simple chordates have evenly distributed yolk. They undergo **holoblastic cleavage**, which involves division of the entire egg.
- In the moderately **telolecithal eggs** of amphibians, a concentration of yolk at the **vegetal pole** slows cleavage so that only a few large cells form there compared with a large number of smaller cells at the **animal pole**.
- The highly telolecithal eggs of reptiles and birds, with a large concentration of yolk at one end, undergo **meroblastic cleavage**, which is restricted to the **blastodisc**.
- Animals whose zygotes have relatively homogeneous cytoplasm exhibit **regulative development**, in which the embryo develops as a self-regulating whole. The relatively rigid developmental patterns of some animals (**mosaic development**) is a consequence of the unequal distribution of cytoplasmic components.
- The **gray crescent** of an amphibian zygote determines the body axis of the embryo.

51.4 Gastrulation (page 1110)

7 Identify the significance of gastrulation in the developmental process and compare gastrulation in the echinoderm (or in amphioxus), the amphibian, and the bird.

- In **gastrulation**, the basic body plan is laid down as three germ layers form: the outer **ectoderm**, the inner **endoderm**, and the **mesoderm** between them.

- The **archenteron**, the forerunner of the digestive tube, forms in some groups; its opening to the exterior is the **blastopore**.
- In gastrulation in the sea star and in amphioxus, cells from the blastula wall invaginate and eventually meet the opposite wall, forming the archenteron.

- In the amphibian, invagination at the vegetal pole is obstructed by large, yolk-laden cells; instead, cells from the animal pole move down over the yolk-rich cells and invaginate, forming the **dorsal lip of the blastopore**.
- In the bird, invagination occurs at the primitive streak, and no archenteron forms.

51.5 Organogenesis (page 1113)

8 Define organogenesis and summarize the fate of each of the germ layers.

- **Organogenesis** is the process of organ formation.
- Ectoderm becomes the nervous system, sense organs, and outer layer of skin (epidermis).
- Mesoderm becomes the notochord, skeleton, muscles, circulatory system, and inner layer of skin (dermis).
- Endoderm becomes the lining of the digestive tube.

9 Trace the early development of the vertebrate nervous system.

- The developing **notochord** is responsible for **induction**, which causes the overlying ectoderm to differentiate as the **neural plate**, the precursor of the central nervous system.
- The cells of the neural plate undergo changes in shape to form the hollow **neural tube**, from which the brain and spinal cord develop.

51.6 Extraembryonic Membranes (page 1115)

10 Give the origins and functions of the chorion, amnion, allantois, and yolk sac.

- The **chorion** and **amnion** derive from ectoderm and mesoderm; the **allantois** and **yolk sac** derive from endoderm and mesoderm.
- The chorion is used in gas exchange. The amnion is a fluid-filled sac that surrounds the embryo and keeps it moist; it also acts as a shock absorber. The allantois stores nitrogenous wastes. The yolk sac makes food available to the embryo.

51.7 Human Development (page 1115)

11 Describe the general course of early human development, including fertilization, the fates of the trophoblast and inner cell mass, implantation, and the role of the placenta.

- Fertilization occurs in the oviduct.
- Cleavage takes place as the embryo is moved down the oviduct.
- In the uterus, the embryo develops into a **blastocyst** consisting of an outer **trophoblast**, which gives rise to the chorion and amnion, and an **inner cell mass**, which becomes the embryo proper. The blastocyst undergoes **implantation** in the endometrium.
- The **umbilical cord** connects the embryo to the **placenta**, the organ of exchange between the maternal and fetal

circulation. The placenta derives from the embryonic chorion and maternal tissue.

12 Contrast postnatal and prenatal life, describing several changes that occur at or shortly after birth that allow the neonate to live independently.

- Human **prenatal** development requires 266 days from the time of fertilization; organogenesis begins during the *first trimester*. After the first two months of development, the embryo is referred to as a **fetus**. Growth and refinement of the organs continue in the second and third trimesters.
- The **neonate** (newborn) must undergo rapid adaptations, especially changes in the respiratory and digestive systems.

Test Your Understanding

Know and Comprehend

1. The mechanism that leads directly to morphogenesis is (a) differential gene expression (b) pattern formation (c) nuclear equivalence (d) cell differentiation (e) cell determination
2. The main function of the acrosome reaction is to (a) activate the egg (b) improve sperm motility (c) prevent interspecific fertilization (d) facilitate penetration of the egg coverings by the sperm (e) cause fusion of the sperm and egg pronuclei
3. The fast block to polyspermy in sea urchins (a) is a depolarization of the egg plasma membrane (b) requires exocytosis of the cortical granules (c) includes the elevation of the fertilization envelope (d) involves the hardening of the jelly coat (e) is a complete block
4. The cleavage divisions of a sea urchin embryo (a) occur in a spiral pattern (b) do not include DNA synthesis (c) do not include cytokinesis (d) are holoblastic (e) do not occur at the vegetal pole
5. Meroblastic cleavage is typical of embryos formed from _____ eggs. (a) moderately telolecithal (b) highly telolecithal (c) isolecithal (d) b and c (e) a, b, and c
6. The primitive groove of the bird embryo is the functional equivalent of the _____ in the amphibian embryo. (a) yolk plug (b) archenteron (c) blastocoel (d) gray crescent (e) blastopore
7. Which of the following are mismatched? (a) endoderm; lining of the digestive tube (b) ectoderm; circulatory system (c) mesoderm; notochord (d) mesoderm; reproductive system (e) ectoderm; sense organs
8. Which of the following has three germ layers? (a) morula (b) gastrula (c) blastula (d) blastocyst (e) trophoblast
9. An unidentified substance (or substances) released from the developing notochord causes the overlying ectoderm to form the neural plate. This phenomenon is known as (a) activation (b) determination (c) induction (d) implantation (e) mosaic development
10. Which of the following consists of both fetal and maternal tissues? (a) umbilical cord (b) placenta (c) amnion (d) allantois (e) yolk sac
11. The embryo proper of a mammal develops from the (a) trophoblast (b) umbilical cord (c) inner cell mass (d) entire blastocyst (e) yolk sac

Apply and Analyze

12. Place the following events of sea urchin fertilization in the proper sequence: 1. fusion of egg and sperm pronuclei 2. DNA synthesis 3. increased protein synthesis 4. release of calcium ions into the egg cytoplasm (a) 4, 3, 1, 2 (b) 3, 2, 4, 1 (c) 2, 3, 1, 4 (d) 1, 2, 3, 4 (e) 4, 1, 2, 3

Evaluate and Synthesize

13. For almost 200 years, scientists debated whether an egg or sperm cell contains a completely formed, miniature human (preformation) or whether structures develop gradually from a formless zygote (epigenesis). Relate these views to current concepts of development.
14. Not all teratogenic medications are banned by the U.S. Food and Drug Administration. Why?
15. **EVOLUTION LINK** Consider the chordate characteristics described in Chapter 32 (notochord, dorsal hollow nerve cord, postanal tail, and pharynx with slits, a deuterostome characteristic). How are they evident in a human embryo? Do they have the same functions in humans as they do in a less specialized chordate, such as amphioxus? Why have they persisted in humans?

16. **EVOLUTION LINK** What is the adaptive value of developing a placenta?
17. **SCIENCE, TECHNOLOGY, AND SOCIETY** As a public health official, what policies might you promote to reduce the incidence of prematurity and/or low birth weight? of malformations at birth?

52 Animal Behavior

KEY CONCEPTS

Suppose that your professor gave you a hypodermic syringe full of poison and told you to find a particular type of insect, one that you had never seen before and that was armed with active defenses. You then had to inject the ganglia of your prey's nervous system (about which you had been taught nothing) with just enough poison to paralyze but not kill it. You would have difficulty accomplishing these tasks, but a solitary wasp no larger than the first joint of your thumb does it all with elegance and surgical precision, without instruction.

Philanthus, the sand wasp (also called beewolf), captures a bee, stings it, and places the paralyzed insect in a burrow excavated in the sand (see photograph). She then lays an egg on her prey. The larva that hatches from that egg devours the bee. *Philanthus* brings provisions to her hidden burrow until autumn, when the larva becomes a hibernating pupa. Her offspring will repeat this behavior, precisely executing each step without ever having seen it done.

An animal's **behavior** is *what it does and how it does it*, usually in response to stimuli in its environment. A dog may wag its tail, a bird may sing, a butterfly may release a volatile sex attractant. Behavior is just as diverse as biological structure and just as characteristic of a given species as its anatomy or physiology. Like its morphology and physiology, an animal's behavior is the product of natural selection on phenotypes and indirectly on the genotypes that code for those phenotypes. Thus, an animal's repertoire of behavior is a set of adaptations that equip it for survival in a particular environment.

Whether biologists study behavior in an animal's natural environment or in the laboratory, they must consider that what an animal does cannot be isolated from the way in which it lives. **Behavioral ecology** is the study of behavior in natural environments from an

- 52.1** Proximate causes of behavior are the immediate causes that explain *how* an animal carries out a specific behavior. Ultimate causes of behavior are the evolutionary explanations for *why* a certain behavior occurs. A behavior is adaptive if its benefits are greater than its costs.
- 52.2** The capacity for behavior is inherited, but behavior is modified in response to environmental experience; the changed behavior is learned behavior.
- 52.3** Biological clocks regulate biological rhythms. Migration is an example of a behavior that involves interactions among biological rhythms, physiology, and the environment.
- 52.4** Optimal foraging is the most efficient way for most animals to obtain food.
- 52.5** Social behavior requires communication among animals in the group. Dominance hierarchies and defense of a territory benefit many social groups.
- 52.6** Sexual selection is a type of natural selection in which individuals with reproductive advantages are selected over others of the same sex and species.
- 52.7** Altruism is a type of cooperative behavior in which one animal behaves in a way that appears to benefit others rather than itself. Kin selection is a form of natural selection that increases inclusive fitness through the successful reproduction of close relatives.
- 52.8** Some bird and mammal species transmit culture, learned behavior common to a population, that one generation teaches to the next.

PHOTO: The sand wasp (*Philanthus triangulum*) at the entrance of her nesting place. How does the wasp “know” how to carry out the complex set of behaviors that ensure her reproductive success?

Premium/UiG/Getty Images

evolutionary perspective. For more than two decades, behavioral ecology has been the main approach of biologists who study animal behavior. Before this approach emerged, the study of animal behavior was called *ethology*, and this term is sometimes still used to refer to the overall study of animal behavior.

In this chapter we consider how an animal's behavior contributes to its reproductive success and to the survival of its species. We discuss types of learning and then focus on the *hows* and *whys* of some key types of behavior, including migration, foraging, and social behavior. We also explore sexual selection and helping behavior.

52.1 Behavior and Adaptation

LEARNING OBJECTIVES

- 1 Distinguish between proximate and ultimate causes of behavior and apply the concepts of ultimate cause and cost–benefit analysis to decide whether a particular behavior is adaptive.
- 2 Describe the interactions of heredity, environment, and maturation in animal behavior.

In considering the reproductive behavior of *Philanthus*, we might wonder *how* she accomplishes her task and *why* she behaves as she does. Early investigators of animal behavior focused on *how* questions. These questions address **proximate causes**, immediate causes such as the genetic, developmental, and physiological processes that permit the animal to carry out the particular behavior.

Today, biologists also ask *why* questions that address the **ultimate causes** of behavior. These questions, which have evolutionary explanations, ask *why* a particular behavior has evolved. Ultimate considerations address costs and benefits of behavior patterns. When studying ultimate causes, we may ask what the adaptive value of a particular behavior might be. An understanding of behavior requires consideration of both proximate and ultimate causes.

Behaviors have benefits and costs

Behavioral ecologists use **cost–benefit analysis** to understand specific behaviors. A behavior may help an animal obtain food or water, protect itself, reproduce, or acquire and maintain territory in which to live. The benefits typically contribute to **direct fitness**, which is an individual's reproductive success, measured by the number of viable offspring it produces. Reproduction is, of course, the key to evolutionary success.

Behaviors also involve costs. For example, while a parent is away hunting for food for its offspring, the youngsters may be killed by predators. Behaviors also have energy costs and costs of missed opportunities to carry out other behaviors. When an animal is foraging for food, it may be missing opportunities to mate. If the benefits are greater than the costs, a behavior is adaptive.

The ultimate cause of a behavior is to increase the probability that the genes of the individual animal will be passed

to future generations. Certain responses may lead to the death of the individual while increasing the chance that copies of its genes will survive through the enhanced production or survival of its offspring or other relatives.

Genes interact with environment

Early biologists debated nature versus nurture, that is, the relative importance of genes compared with environmental experience. They defined **innate behavior** (inborn behavior, popularly referred to as *instinct*) as genetically programmed and **learned behavior** as behavior that has been modified in response to environmental experience. More recently, behavioral ecologists have recognized that no true dichotomy exists. All behavior has a genetic basis. Even the *capacity* for learned behavior is inherited. However, behavior is modified by the environment in which an animal lives; behavior is a product of the interaction between genetic capacity and environmental influences. Thus, behavior begins with an inherited framework that experience can modify.

We can think of a range of behaviors from the more rigidly genetically programmed types through those that, although they have a genetic component, are extensively developed through experience. The sand wasp *Philanthus*, discussed in the chapter introduction, efficiently carries out a sequence of behaviors that depends mainly on genetic programming. How to dig the burrow, how to cover it, how to kill the bees—these behaviors are genetically determined. Yet some of her behavior is learned. There is no way that her ability to locate the burrow could be genetically programmed. Because a burrow can be dug only in a suitable spot, its location must be learned *after* it is dug. When *Philanthus* covers her burrow with sand, she takes precise bearings of its location by circling the area a few times before flying off again to hunt.

Dutch ethologist Niko Tinbergen studied this behavior of *Philanthus*. He surrounded the wasp's burrow with a circle of pine cones as potential landmarks (**FIG. 52-1**). Before the wasp returned with another bee, Tinbergen rearranged or removed the pine cones. Without them, the wasp could not find her burrow. When Tinbergen moved the pine cones to an area where there was no burrow, the female wasp responded as though the burrow were there. When the investigator completely removed them, the female seemed very confused. Only when Tinbergen restored the cones to their original location could the wasp find her burrow.

When Tinbergen substituted a ring of stones for the cones, the wasp responded as though the burrow were in the center of the stones. Thus, *Philanthus* responded to the *arrangement* of the cones rather than to the cones themselves. Tinbergen's findings demonstrated that for *Philanthus*, learning the landmarks surrounding the burrow was critical for burrow locating.

Studies of fruit fly courtship and mating have provided interesting examples of interaction between genes and behavior. A ritual consisting of a complex sequence of steps, almost like a dance, must occur before mating takes place. This courtship ritual involves an exchange of visual, auditory, tactile, and chemical signals between the male and female. J.B. Hall of Brandeis

Key Experiment

How does *Philanthus* locate her burrow when she returns to provision it with food?

HYPOTHESIS: *Philanthus* uses visual cues to locate her burrow.

EXPERIMENT:

- 1 While *Philanthus* was in the burrow, Tinbergen placed a circle of pine cones around its entrance.
- 2 While the wasp was out foraging, Tinbergen moved the cones to a new position (away from the burrow entrance).
- 3 In a second experiment, Tinbergen left the pine cones around the burrow but rearranged them in a triangle shape in the wasp's absence. Nearby, he made a circle of stones.

RESULTS AND CONCLUSION:

- 1 When *Philanthus* emerged from her burrow, she responded to the circle of pine cones by circling the site, an orientation flight. When she returned with prey, she flew to the middle of the circle of pine cones to locate the small, concealed entrance to her burrow.
- 2 When Tinbergen relocated the circle of pine cones away from the burrow, *Philanthus* flew to the middle of the new circle because she had learned the position of the burrow in relation to the cones.
- 3 When Tinbergen rearranged the cones in the shape of a triangle and made a circle of stones nearby, *Philanthus* flew to the middle of the circle of stones.

Philanthus used visual cues (a circle of cones) to learn the location of her burrow. Later she looked for the circle of cones to locate her burrow. She responded to the *arrangement* of cones rather than to the cones themselves. Learning landmarks (visual cues) is critical for locating the burrow.

Figure 52-1 Niko Tinbergen's experiments determining how the wasp *Philanthus* locates her burrow

PREDICT Imagine that when *Philanthus* first emerged from her nest, the investigator scared her away before she could orient herself to any visual cues. Would she be able to find her burrow?

University and his colleagues identified more than a dozen genes controlling these actions, suggesting that courtship behavior is largely inherited and preprogrammed. Nevertheless, the fruit fly has the capacity to learn from experience, a capacity that, of course, is also inherited.

The interaction between genes and environment has been studied in many vertebrates. Several species of the lovebird (*Agapornis*) differ not only in appearance but in behavior. One species uses its bill to transport small pieces of bark for building a nest. Another species tucks nest-building materials under its rump feathers. Hybrid birds attempt to tuck material under their feathers and then try to carry it in their bills, repeating the pattern several times. Eventually, most of the birds carry the material in their bills, but it takes them up to three years to perfect this behavior, and most continue to make futile attempts to tuck material into their feathers. Thus, the method of transporting materials is inherited but somewhat flexible. (In nature, hybrids would likely experience dramatically reduced fitness because of the long delay in breeding onset.)

Behavior depends on physiological readiness

Although behavior involves all body systems, it is influenced mainly by the nervous and endocrine systems. The capacity for behavior depends on the genetic characteristics that govern the development and functions of these systems. Before an animal can exhibit any pattern of behavior, it must be physiologically ready to produce the behavior. For example, breeding behavior does not ordinarily occur among birds or most mammals unless sufficient concentrations of sex hormones are present in their blood. A human baby cannot walk until its neurons and muscles are sufficiently developed. These states of physiological readiness are themselves produced by a continuous interaction with the environment. The level of sex hormones in a bird's blood may

be determined by seasonal variations in day length. The baby's muscles develop with experience as well as age.

Several factors influence the development of song in male white-crowned sparrows (generally only male songbirds sing a complex song). These birds show considerable regional variation in their song. During early development, young sparrows normally hear adult males sing the distinctive song of their population. Days 10 to 52 after hatching are a critical period for learning the song. When he is several months old, a young male sparrow “practices” the song over several weeks until he eventually sings in the local “dialect.”

In laboratory experiments, birds kept in isolation and deprived of the acoustic experience of hearing the song of mature males eventually sing a poorly developed but recognizable white-crowned sparrow song. When a young white-crowned sparrow is permitted to interact socially with a strawberry finch (which belongs to a different genus of birds), it learns the song of the finch rather than its own species-specific song. This learning occurs even if the white-crowned sparrow can hear the song of other sparrows but does not interact with them socially. From these experiments, investigators have concluded that the white-crowned sparrow is hatched equipped with a rough genetic pattern of its song, but social and acoustic stimuli are important in developing the ability to sing its specific song.

Many behavior patterns depend on motor programs

Many behaviors that we think of as automatic depend on coordinated sequences of muscle actions called **motor programs**. Some motor programs—for example, walking in newborn gazelles—seem mainly innate. Others, such as walking in human infants, have a greater learned component.

A classic example of a motor program in vertebrates is egg rolling in the European graylag goose (FIG. 52-2). Once activated by a simple sensory stimulus, egg-rolling behavior continues to completion regardless of sensory feedback. There is little flexibility. Behavioral ecologists call this behavior a

behavioral pattern. Certain behavioral patterns can be elicited by a **sign stimulus**, or *releaser*, a simple signal that triggers a specific behavioral response. A wooden egg is a sign stimulus that elicits egg-rolling behavior in the graylag goose.

In a set of classic experiments performed in 1951, Tinbergen showed that the red stripe on the ventral surface (belly) of a male stickleback fish is a sign stimulus. The ventral surface of the male stickleback is normally silver but turns red at the beginning of the breeding season. The male stickleback selects a territory, builds a nest, and defends his territory against rival males. After a female lays her eggs, she leaves; the male then guards the eggs and, later, the newly hatched fish.

Tinbergen showed that the red stripe triggers aggressive behavior by a male when his territory is being invaded. Tinbergen found that crude models painted with a red belly were more likely to be attacked than more realistic models lacking the red belly (FIG. 52-3). Aggressive behavior is triggered by the red belly rather than by recognition based on a combination of features.

CHECKPOINT 52.1

- In what ways are the behaviors of *Philanthus*, the sand wasp, adaptive?
- **CONNECT** Give an example showing that behavior capacity is inherited and is modified by learning.
- **CONNECT** How does physiological readiness affect innate behavior? How does it affect learned behavior?

52.2 Learning: Changing Behavior as a Result of Experience

LEARNING OBJECTIVE

- 3 Discuss the adaptive significance of habituation, imprinting, classical conditioning, operant conditioning, and cognition.

Figure 52-2 Egg-rolling behavior in the European graylag goose (*Anser anser*)

In this rigid behavioral pattern, the goose reaches out by extending her neck and uses her bill to pull the egg back into the nest. If the investigator quickly removes the egg while the goose is in the process of reaching for it or pulling it back, the goose continues the behavior to completion, as though pulling the now-absent egg back to the nest.

Key Experiment

What triggers aggressive behavior in the male stickleback?

HYPOTHESIS: The red ventral surface (belly) of a male stickleback is a sign stimulus that triggers aggressive behavior in other male sticklebacks.

EXPERIMENT: Niko Tinbergen presented male sticklebacks with two series of models.

- 1 The models in the neutral series were the neutral color of the male in the nonbreeding season.
- 2 The models in the red series were red on the ventral surface.

RESULTS AND CONCLUSION: The male fish did not attack realistic models of another male stickleback when they lacked a red belly. The male fish did attack other models that had red ventral surfaces, even when their shapes were unrealistic.

The red belly of another male stickleback is a sign stimulus (releaser) that activates stereotyped aggressive behavior in a male stickleback.

SOURCE: N. Tinbergen, *The Study of Instinct* (Oxford University Press, New York, 1951).

Figure 52-3 Niko Tinbergen's experiments on aggressive behavior in the male stickleback fish

PREDICT Imagine that a male stickleback has a mutation that prevents him from responding to the red belly of another male stickleback. How might that affect his direct fitness?

Based on our discussion thus far, it should be clear that much inherited behavior can be modified by experience. **Learning** involves persistent changes in behavior that result from experience. The capacity to learn new responses to new situations

is adaptive, enabling animals to survive as their environment changes.

Learning abilities are biased; information most important to survival appears most easily learned. It may have taken a rat a dozen trials to learn the artificial task of pushing a lever to get a reward. However, the same rat learns from *one* experience to avoid a food that has made it ill. People who poison rats to get rid of them can readily appreciate the adaptive value of this learning ability. Such quick learning in response to an unpleasant experience forms the basis of **warning coloration**, or **aposematic coloration**, which is found in many poisonous insects and brilliantly colored, but distasteful, bird eggs. Once made ill by such a meal, predators quickly learn to avoid them. In the following sections, we consider several types of learning, including habituation, imprinting, classical conditioning, operant conditioning, and cognition.

An animal habituates to irrelevant stimuli

Habituation is a type of learning in which an animal learns to ignore a repeated, irrelevant stimulus, that is, one that neither rewards nor punishes. Pigeons gathered in a city park learn by repeated harmless encounters that humans are not dangerous to them and behave accordingly. This behavior benefits them. A pigeon intolerant of people might waste energy by flying away each time a human approached and might not get enough to eat. Many African animals habituate to humans on photo safari and to the vans that transport them (FIG. 52-4). Urban humans habituate to the noise of traffic. In fact, many urban dwellers report that they do not sleep well when they visit a quiet rural area.

McMurray Photography

Figure 52-4 Habituation

After repeated safe encounters with vans transporting humans on photo safari, many animals, including giraffes, zebras, antelope, and lions in the Serengeti, learn to ignore them. Elephants typically ignore the vans unless the driver provokes them by moving too close. In that event an elephant may challenge and even charge the van.

Imprinting occurs during an early critical period

Anyone who has watched a mother goose with her goslings must have wondered how she can “keep track” of such a horde of almost identical little creatures tumbling about in the grass, let alone distinguish them from those of another goose (FIG. 52-5). Although she can recognize her offspring to some extent, basically *they* have the responsibility of keeping track of *her*. The survival of a gosling requires that it quickly learn to discriminate its mother (care provider) from other geese.

Imprinting, a type of social learning based on early experience, has been studied in some mammals as well as birds. It occurs during a *critical period*, usually within a few hours or days after birth (or hatching). Konrad Lorenz, an Austrian physician and early ethologist, discovered that a newly hatched bird imprints on the first moving object it sees, even a human or an inanimate object such as a colored sphere or light. Although the process of imprinting is genetically determined, the bird *learns* to respond to a particular animal or object.

Among many types of birds, especially ducks and geese, older embryos can exchange calls with their nest mates and parents through the porous eggshell. When they hatch, at least one parent is normally on hand, emitting the characteristic sounds with which the hatchlings are already familiar. If the parent moves, the chicks follow. This movement and the sounds produce imprinting. During a brief critical period after hatching, the chicks learn the appearance of the parent.

Imprinting in some mammals depends on scent. Baby shrews, for example, become imprinted on the odor of their mother (or any female nursing them). In many species the mother also learns to distinguish her offspring during a critical period. In some species of hoofed mammals, such as sheep, the mother will accept her offspring for only a few hours

after its birth; if the mother and her offspring are kept apart past that time, the young are rejected. Normally, the mother learns to distinguish her own offspring from those of others by olfactory cues.

In classical conditioning, a reflex becomes associated with a new stimulus

In **classical conditioning**, an association forms between some normal body function and a new stimulus. If you have observed dog or cat behavior, you know that the sound of a can opener at dinnertime can captivate a pet’s attention! Early in the 20th century, Ivan Pavlov, a Russian physiologist, discovered that if he rang a bell just before he fed a dog, the dog learned to associate the sound of the bell with food. Eventually, the dog salivated even when the bell was rung in the absence of food (FIG. 52-6).

Pavlov called the physiologically meaningful stimulus (food, in this case) the *unconditioned stimulus*. The normally irrelevant stimulus (the bell) that became a substitute for it was the *conditioned stimulus*. Salivating to the food was an *unconditioned response*, whereas salivating to the bell was a *conditioned response*. Because a dog does not normally salivate at the sound of a bell, the association was clearly learned. It could also be forgotten. If the bell no longer signaled food, the dog eventually stopped responding to it. Pavlov called this latter process **extinction**. Classical conditioning can be adaptive. For example, if an animal is threatened by a predator in a particular area, it associates the place with danger and avoids that area in the future. In this case the animal learns to *avoid* a negative stimulus rather than to expect a reward.

In operant conditioning, spontaneous behavior is reinforced

In **operant conditioning**, the animal must do something to gain a reward (positive reinforcement) or avoid punishment. Operant conditioning has been studied in many animals, including flatworms, insects, spiders, birds, and mammals. In a typical laboratory experiment, a rat is placed in a cage containing a movable bar. When random actions of the rat result in pressing the bar, a pellet of food rolls down a chute to the rat. Thus, the rat is positively reinforced for pressing the bar. Eventually, the rat learns the association and presses the bar to obtain food.

In negative reinforcement, removal of a stimulus increases the probability that a behavior will occur. For example, a rat may be subjected to an unpleasant stimulus, such as a low-level electric shock. When the animal presses a bar, this negative reinforcer is removed.

Many variations of these techniques have been developed. A pigeon may be trained to peck at a lighted circle to obtain food, a chimpanzee may learn to perform some task to get tokens that can be exchanged for food, and children may learn to sit quietly in their seats at school to obtain the teacher’s praise.

Figure 52-5 Imprinting

Parent–offspring bonds generally form during an early critical period. The goslings have imprinted on their mother, an Egyptian goose (*Alopochen aegyptiaca*). Photographed in Ndutu, Tanzania, Africa.

Key Experiment

Can an animal learn to respond in a certain way to a new (previously neutral) stimulus by associating it with a familiar stimulus?

HYPOTHESIS: A dog can be conditioned to salivate at the sound of a bell.

EXPERIMENT: Ivan Pavlov presented food (the unconditioned stimulus) to a dog and observed that the dog salivated (unconditioned response). He then rang a bell (conditioned stimulus) just before he gave food to the dog. Pavlov repeated this pairing several times. Then he sounded the bell in the absence of food.

RESULTS AND CONCLUSION: The dog became conditioned to salivate at the sound of the bell alone. When a bell (conditioned stimulus) is paired with food (an unconditioned stimulus), an animal learns to associate them. The animal then salivates to the sound of the bell alone (conditioned response).

SOURCE: I.P. Pavlov, *Conditioned Reflexes: An Investigation of the Physiological Activity of the Cerebral Cortex*, translated by G.V. Anrep (Oxford University Press, London, 1927).

Figure 52-6 Classical conditioning: Pavlov's dog

PREDICT A young boy was bitten by a dog. He was startled, scared, and hurt, and he cried. A few weeks later, he sees another dog. How do you think he is likely to respond?

Operant conditioning plays a role in the development of some behaviors that appear genetically programmed. An example is the feeding behavior of gull chicks. Herring gull chicks peck the beaks of the parents, which stimulates the parents to regurgitate partially digested food for them. The chicks are attracted by two stimuli: the general appearance of the parent's beak with its elongated shape and distinctive red spot, and its downward movement as the parent lowers its head. Like the rat's chance pressing of the bar, the

chicks' initial exploratory pecking behavior is sufficiently functional for them to get their first meal, but they waste a lot of energy in pecking. Some pecks are off target and are therefore not rewarded. However, pecking behavior becomes more efficient with practice. Thus, a behavior that might appear to be entirely genetic is improved by learning (FIG. 52-7).

Animal cognition is controversial

Cognition is the process of gaining and using knowledge; it includes thinking, processing information, learning, reasoning, and awareness of thoughts, perceptions, and self. Cognition allows us to carry out high-level mental functions. For example, we can make difficult decisions; solve problems, including mathematical problems; plan; and develop and comprehend languages. How closely animal cognition approximates human thought processes has been hotly debated and is the focus of a great deal of research.

Cognition allows some animals to *problem solve*. For example, a chimpanzee presented with a new problem is likely to have the insight to make new associations from tasks it has learned previously. The chimp can adapt prior knowledge and experience to solve the current problem (FIG. 52-8). Primates are especially skilled at cognition and problem solving, but some other mammals and a few birds, notably some crows (e.g., ravens), also appear to problem solve to some degree.

Figure 52-7 Operant conditioning

When the gull chick pecks its parent's beak, the chick is positively reinforced with food. After many tries, the chick learns to be more accurate in begging for food from its parent.

Play may be practice behavior

Perhaps you have watched a kitten pouncing on a dead leaf or practicing a carnivore neck bite or a hind-claw disemboweling stroke on a littermate without causing injury. Many animals, especially young birds and mammals, appear to practice adult patterns of behavior while they play (FIG. 52-9). They may improve their ability to escape, hunt, kill prey, or perform sexual behavior. Play may be an example of operant

Figure 52-9 Cheetah cubs playing

Play may serve as a means of practicing behavior that will be useful later in life, such as when hunting, fighting for territory, or competing for mates. These cheetah cubs (*Acinonyx jubatus*) were photographed in Kenya, Masai Mara National Reserve.

conditioning in action. Hypotheses for the ultimate causes of play behavior include exercising, learning to coordinate movements, and learning social skills. Of course, there could be other unknown explanations.

CHECKPOINT 52.2

- **CONNECT** How is imprinting adaptive?
- **CONNECT** How is operant conditioning adaptive?

52.3 Behavioral Responses to Environmental Stimuli

LEARNING OBJECTIVES

- 4 Give examples of biological rhythms and describe some of the physiological mechanisms responsible for them.
- 5 Analyze costs and benefits of migrations and distinguish between directional orientation and navigation.

Think of the many variations that take place in our natural surroundings: cycles of day and night, changes in length of day with changing seasons, lunar cycles, high and low tides, changes in weather, and variations in amount and distribution of food. Biologically successful animals are physiologically and behaviorally adapted to the continuous changes that take place in their environment.

Biological rhythms regulate many behaviors

The biochemical, physiological, and behavioral responses that animals make to the periodic changes in the environment are referred to as **biological rhythms**. Biologists have identified many types of biological rhythms, including daily, monthly, and annual rhythms. Among many animals, physiological cycles such as body-temperature fluctuations and hormone secretion are rhythmic. Human body temperature, for example, follows a typical daily curve, with the lowest temperature early in the morning and the highest in the late afternoon. (Women also have a monthly temperature rhythm, with the highest body temperature during the last half of the menstrual cycle.) Biological rhythms regulate many behaviors, including activity, sleep, feeding, drinking, reproduction, and migration.

The behavior of many animals, like the activities of many plants, is organized around **circadian rhythms** (circadian means “approximately one day”), which are daily, 24-hour cycles of activity. **Diurnal animals**, such as honeybees and pigeons, are most active during the day. Most bats, moths, and cats are **nocturnal animals** and are most active during the hours of darkness. **Crepuscular animals**, like many mosquitoes and fiddler crabs, are busiest at dawn, dusk, or both. Generally, there are

ecological reasons for these patterns. If an animal's food is most plentiful in the early morning, for example, its cycle of activity must be regulated so that it becomes active shortly before dawn.

Some biological rhythms of animals reflect the *lunar cycle* (moon). The most striking rhythms are those in marine organisms that are attuned to changes in tides and phases of the moon. For instance, a combination of tidal, lunar, and annual rhythms governs the reproductive behavior of the grunion, a small fish that lives off the Pacific coast of North America. Grunions swarm from April through June on those three or four nights when the highest tides of the year occur. At precisely the high point of the tide, the fish squirm onto the beach and deposit eggs and sperm in the sand. They return to the sea in the next wave. By the time the next tide reaches that portion of the beach 15 days later, the young fish have hatched in the damp sand and are ready to enter the sea. This synchronization may help protect fish eggs from aquatic predators.

An animal's metabolic processes and behavior are typically synchronized with the cyclic changes in its external environment. Its behavior anticipates these regular changes. The little fiddler crabs of marine beaches often emerge from their burrows at low tide to engage in social activities such as territorial disputes. To avoid being washed away, they must return to their burrows before the tide returns. How do the crabs "know" that high tide is about to occur? One might guess that the crabs recognize clues present in the seashore. However, when the crabs are isolated in the laboratory away from any known stimulus that could relate to time and tide, their characteristic behavioral rhythms persist.

Many biological rhythms are regulated by *internal* timing mechanisms that serve as **biological clocks**. As illustrated by the fiddler crabs, these timing mechanisms do not simply respond to environmental cues but are capable of sustaining biological rhythms independently. Such internal clocks have been identified in almost every eukaryote as well as in some prokaryotes. Molecular biologists have demonstrated that genes control biological clocks. In *Drosophila* seven genes produce clock proteins that seem to interact in feedback loops in many cell types both inside and outside the nervous system. Researchers have identified similar genes and proteins in many animal groups, including mammals. The principal clock is located in specific areas of the central nervous system.

In mammals, the master clock is located in the **suprachiasmatic nucleus (SCN)** in the hypothalamus (see Chapter 42). This SCN clock generates approximately 24-hour cycles even without input from the environment. However, the SCN-generated cycles are normally adjusted every day based on visual input received from the retina. Signals from the retina reflecting changes in light intensity adjust internal circadian rhythms to light–dark cycles in the environment. The SCN sends rhythmic signals, in the form of neuropeptides, to the **pineal gland**, an endocrine gland located in the brain. In response, the pineal gland secretes *melatonin*, a hormone that promotes sleep in humans. Clock genes in the SCN are turned on and off by the very proteins they encode, setting up feedback loops that have a 24-hour cycle.

In addition to the master clock, most cells have timing mechanisms that use many of the same clock proteins. These peripheral clocks may function independently of the SCN.

Environmental signals trigger physiological responses that lead to migration

Ruby-throated hummingbirds cross the vast distance of the Gulf of Mexico twice each year. The sooty tern travels across the entire South Atlantic from Africa to reach its tiny island breeding grounds south of Florida. Birds, butterflies, fishes, sea turtles, wildebeest, zebras, and whales are among the many animals that travel long distances. Behavioral ecologists define **migration** as a periodic long-distance travel from one location to another. Many migrations involve astonishing feats of endurance and navigation.

Why do animals migrate? Ultimate causes of migration apparently involve the advantages of moving from an area that seasonally becomes less hospitable to a region more likely to support reproduction or survival. Seasonal changes include shifts in climate, availability of food resources, and safe nesting sites. For example, as winter approaches, many birds migrate to a warmer region.

Proximate causes of migration include signals from the environment that trigger physiological responses leading to migration. In migratory birds, for example, the pineal gland senses changes in day length and then releases hormones that cause restless behavior. The birds show an increased readiness to fly and to fly for longer periods.

Migration has costs and benefits An interesting example of migration is the annual journey of millions of monarch butterflies (*Danaus plexippus*) from Canada and the continental United States to Mexico, a journey of 2520 km (about 1520 mi) for some. Their dramatic annual migration appears related to the availability of milkweed plants on which females lay their eggs. On hatching, the larvae (caterpillars) feed on the leaves of the milkweed plant. In cold regions, these plants die in late autumn and grow again with the warmer weather of spring.

The wintering destinations of monarchs also may be determined by temperature and humidity. Possible benefits include the opportunity to winter in an area that offers an abundant food supply, nonfreezing temperatures, and moist air. Thus, the investment made by migrating monarch butterflies in their long journey increases their chances of surviving the winter.

The benefits of migration are not without costs in time, energy, and even survival. Many weeks may be spent each year on energy-demanding journeys. Some animals may become lost or die along the way from fatigue or predation. When in unfamiliar areas, migrating individuals are often at greater risk from predators.

In recent years, human activities have interfered with migrations of many kinds of animals. For example, after millions of years of biological success, survival of sea turtles is threatened by fishing and shrimping nets in which they become entangled. As a result, thousands of migrating turtles drown each year. Sea turtles also die as a result of contamination from oil spills, entanglement in discarded fishing line, and ingestion of floating plastic bags that they mistake for jellyfish.

Animals find their way using directional orientation and navigation How do migrating animals find their way?

Kenneth Lohmann

Figure 52-10 Navigation by light and magnetic field

To study turtle navigation, researcher Kenneth Lohmann harnessed leatherback turtles (*Dermochelys coriacea*), such as this hatchling, and wired them to a computer that recorded their swimming direction.

Directional orientation refers to travel in a specific direction. To travel in a straight line toward a destination requires a sense of direction, or **compass sense**. Many animals use the sun to orient themselves. Because the sun appears to move across the sky each day, an animal must have a sense of time. Biological clocks seem to sense time and regulate circadian rhythms.

Navigation is more complex than traveling in a specific direction. Navigation requires both compass sense and **map sense**, which is an “awareness” of location. Navigation involves the use of cues to change direction when necessary to reach a specific destination. When navigating, an animal must integrate information about distance and time, as well as direction.

DNA tests confirm that loggerhead sea turtles that hatch on Florida beaches along the Atlantic swim hundreds of miles across the ocean to the Mediterranean Sea, an area rich in food. Several years later, those that survive to become adults mate, and the females navigate back, often to the same beach, to lay their eggs. Their journey requires both compass sense and map sense.

Marine biologist Kenneth Lohmann of the University of North Carolina fitted hatchling turtles with harnesses connected to a swivel arm in the center of a large tank (FIG. 52-10). A computer connected to the swivel arm recorded the turtles’ swimming movements. By manipulating light and magnetic fields, Lohmann demonstrated that both these environmental cues are important in turtle migration. The turtles swam toward the east until Lohmann reversed the magnetic field. The turtles then reversed their direction to swim toward the new “magnetic east,” which was now actually west. Subsequent research suggests that young turtles use wave direction to help set magnetic direction preference.

Some biologists suspect that turtles also use their sense of smell to guide them, particularly to guide the females to the very same beach to lay their eggs. Similarly, adult salmon use the unique odors of different streams to help find their way back to the same stream from which they hatched.

Birds and some other animals that navigate by day rely on the position of the sun (our local star); those that travel at night use the stars to guide them. When birds see the star patterns of the night sky, they fly in the appropriate migration

direction for their species, even when they have had no opportunity to learn this feat from other birds.

Studies by Stephen Emlen of Cornell University showed that young indigo buntings learn the constellations using the position of the North Star as their reference point. (Other stars in the Northern Hemisphere appear to rotate about the North Star.) When Emlen rearranged the constellations in a planetarium sky, birds in the planetarium learned the altered patterns of stars and later attempted to fly outside in a direction consistent with the artificial pattern. These and other studies suggested that birds have a genetic ability to learn constellation patterns and use them to orient during migration.

Investigators have long observed that some species of birds navigate even when the sky is overcast and they cannot see the stars. They hypothesized that these birds use Earth’s magnetic field to navigate. Studies of garden warblers indicate that as these birds make their way from central Europe to Africa each winter, they navigate both by the stars and by Earth’s magnetic field. The warblers use stars to determine the general direction of travel and then use magnetic information to refine and correct their course. In addition to birds and sea turtles, honeybees, some fishes, and some other animals are sensitive to Earth’s magnetic field and use it as a guide.

CHECKPOINT 52.3

- **CONNECT** Why is it adaptive for some species to be diurnal but for others to be nocturnal or crepuscular?
- What is the difference between directional orientation and navigation?

52.4 Foraging Behavior

LEARNING OBJECTIVE

- 6 Define *optimal foraging behavior* and explain how it is adaptive.

Feeding behavior, or **foraging**, involves locating and selecting food as well as gathering and capturing food. Some behavioral ecologists study the costs and benefits of searching for and selecting certain types of food as well as the mechanisms used to locate prey. For example, many camouflage strategies have evolved that make potential prey difficult to detect. As predators experience repeated success in locating a particular prey species, they are thought to develop a *search image*, a constellation of cues that help them identify hidden prey.

Why do grizzly bears spend hours digging arctic ground squirrels out of burrows while ignoring larger prey such as caribou? It is more energy efficient to dig for squirrels because the bears’ efforts most probably will be rewarded, whereas caribou are more likely to escape, leaving the bears hungry. This behavior is an example of **optimal foraging**.

the most efficient way for an animal to obtain food. According to *optimal foraging theory*, when animals forage, they maximize their energy intake per unit of foraging time. When animals maximize energy obtained per unit of foraging time, they may maximize their reproductive success. Many factors, such as avoiding predators while foraging, must be considered in determining efficient or optimal strategies.

In habitats where the most-preferred food items are abundant and an animal does not have to travel far to obtain them, animals can afford to be selective. In contrast, the optimal strategy in poor habitats, where it takes longer to find the best food items, is to select less-preferred items. Animals may learn to forage efficiently through operant conditioning, that is, by randomly trying various strategies and selecting the one associated with the most rewards (and the fewest hunger pangs at the end of the day).

Foraging is also affected by the forager's risk of predation. British biologist Guy Cowlishaw studied foraging behavior in a population of baboons in Namibia. He found that the baboons spent more time foraging in a habitat in which food was relatively scarce than in an area with more-abundant food that had a high risk of predation by lions and leopards.

Lions live, and often forage, in social units called *prides*. A pride typically consists of a group of related adult females, their cubs, and unrelated males. Biologist Craig Packer of the University of Minnesota and his research team studied lion behavior in Serengeti National Park, Tanzania. Packer radio-collared at least one female in each of 21 prides and tracked them for several years. During the season when prey was abundant, lions hunted wildebeest, gazelle, and zebra that migrated into the area. When these herds migrated out of the area during the dry season, these prey become scarce, and lions fed mainly on warthog and Cape buffalo.

Packer reported that when prey was abundant, the size of the foraging group had little effect on daily food intake. Whether a lion hunted individually or in small (two to four females) or large (five to seven) groups, food was captured by individuals or groups of any size. During the season when prey was scarce, however, lions were more successful if they hunted alone or in large groups (FIG. 52-11). Nevertheless, Packer's data from radio-collared lions indicated that females typically foraged in as large a group as they could, even if the group consisted of three or four females, an approach that decreased foraging efficiency. Thus, selection pressure seems to be stronger to protect cubs and defend territory against larger prides than to forage maximally (alone).

Figure 52-11 Optimal foraging and group size in lions

During times of prey scarcity, optimal foraging is related to group size: lions hunt most successfully alone or in large groups of five to seven. Observations of group size suggest that the benefits of optimal defense often outweigh the benefits of optimal foraging. Based on data from Packer, C., D. Scheel, and A.E. Pusey, "Why Lions Form Groups: Food Is Not Enough," *American Naturalist*, Vol. 136 (July 1990).

52.5 Costs and Benefits of Social Behavior

LEARNING OBJECTIVES

- 7 Analyze social behavior in terms of costs and benefits, and compare different types of social groups, including societies of social insects.
- 8 Describe common modes of animal communication, including signaling by pheromones.
- 9 Compare the costs and benefits of dominance hierarchies and of territoriality.

The mere presence of more than one individual does not mean that a behavior is social. Many factors of the physical environment bring animals together in *aggregations*, but whatever interaction they experience may be circumstantial. A light shining in the dark is a stimulus that draws large numbers of moths, and the high humidity under a log attracts wood lice. Although these aggregations may have adaptive value, they are not truly social because the animals are not communicating with one another.

We can define **social behavior** as the interaction of two or more animals, usually of the same species. In the same way that natural selection led to the evolution of behaviors in response to environmental factors, natural selection has resulted in the evolution of social behavior. In this chapter we examine several familiar types of social behavior, including

CHECKPOINT 52.4

- What is optimal foraging?
- **CONNECT** How is optimal foraging adaptive?

communication, living together, dominance behaviors, territoriality, mating rituals, parenting, and helping behavior.

An organized **society** is an actively cooperating group of individuals belonging to the same species and often closely related. Many insects, such as tent caterpillars, which spin communal nests, cooperate socially. A school of fish, a flock of birds, a pack of wolves, and a hive of bees are other examples of societies. Some societies are loosely organized, whereas others are elaborately structured.

Many animals benefit from living in groups. Schools of fishes tend to confuse predators, so individuals within the school may be less vulnerable to predators than a solitary fish would be (see Fig. 53-1b). Zebra stripes appear to be a visual antipredator adaptation. When viewed from a distance, the stripes tend to visually break up the form of the animal so that individuals cannot be distinguished. A herd of zebras confuses predators, whereas a solitary animal is easy prey for lions, cheetahs, or spotted hyenas (FIG. 52-12).

Social foraging is an adaptive strategy used routinely by many animal species. A pack of wolves has greater success in hunting than an individual wolf would have. Among some birds of prey, such as certain hawks, group hunting locates prey more quickly than hunting alone.

Social behavior has benefits in addition to defense against predators and in some cases more successful foraging. Living together provides opportunities for interfering with reproduction of competitors, such as destroying their eggs. Social living also provides the opportunity to receive help from others in the group. Thus, for many types of animals, social behavior increases direct fitness. However, social behavior also has certain costs. Living together means increased competition for food and habitats, increased risk of attracting predators, and increased risk of transmitting disease. In addition, time and energy must often be invested in gaining and maintaining social status.

Figure 52-12 Social behavior in zebras

The social unit consists of a fairly stable group of females with young and a dominant stallion. When viewed from a distance, the stripes of a group of zebras serve as camouflage, confusing predators.

Communication is necessary for social behavior

One animal can influence the behavior of another only if the two of them can exchange mutually recognizable signals (FIG. 52-13). *Communication* is most evident when one animal performs an act that changes the behavior of another. Animals may communicate to hold a group together, warn of danger, signal social status, indicate willingness to accept or provide care, identify members of the same species, or indicate sexual maturity or readiness to mate. Communication may also be important in finding food, as in the elaborate dances of honeybees. Animals use electrical, tactile, visual, auditory, and chemical signals to transmit information to one another.

Certain fishes (gymnotids) emit electric pulses that generate electric fields in the water. These electric pulses can be used for navigation and communication, including territorial threat, in a

(a) A male spring peeper frog (*Hyla crucifer*) calling to locate a mate.

(b) **Communicating with language.** Chimpanzee Tatu (top) is signing “food” to Washoe (below), the first chimp to learn American Sign Language from a human. Washoe then taught other chimps how to sign.

Figure 52-13 Animal communication

fashion similar to bird vocalization. As Harvard sociobiologist Edward O. Wilson said, “The fish, in effect, sing electrical songs.”

Examples of animal touch include grooming and sharing food. Social insects, such as ants, groom and stroke one another with their antennae and mouthparts. Many types of bird chicks stimulate their parents to feed them by pecking at their beaks.

Visual signals can be transmitted quickly Visual signals are fast, communicate a great deal of information, and indicate the location and position of the animal sending the signal. An animal's own body, such as its coloration, may serve as the visual message. Numerous species communicate with visual displays that serve as social signals. For example, many birds present visual displays along with their songs.

Auditory signals can be conveyed in the dark Most animals cannot communicate effectively with visual signals when it is dark. However, animals can hear at night as well as during the day. Auditory signals can also be transmitted over longer distances than visual signals. Sound can move in all directions at once, and an auditory signal can be rapidly terminated. Most animals that communicate with auditory signals use **calls**, short, simple sounds. Birds and mammals use more complex auditory signals. In many bird species, males announce their presence and willingness to interact socially by singing. Some birds respond to a particular sound by matching it.

Some mammals, in addition to humans, learn to produce new sounds. These mammals include bats, cetaceans (dolphins and whales), elephants, seals, baboons, and orangutans. Orcas (formerly known as killer whales) communicate by sounds and songs. Members of a given pod (social group) have an average of 12 different calls, which vary in pitch and duration and appear to reflect their “emotional” state.

Bottlenose dolphins match sounds in communicating. These dolphins respond to the whistles of members of their own species by imitating and emitting the same sound. Researchers suggest that vocal matching was important in the evolution of human language.

Some animals communicate by scent Dogs and wolves mark territory by frequent urination. Antelopes, deer, and cats rub facial gland secretions on conspicuous objects in their vicinity and urinate on the ground. **Pheromones** are chemical signals secreted into the environment that convey information between members of a species. These small, volatile molecules provide a simple, widespread means of communication. Animals use pheromones to communicate danger, ownership of territory, and availability for mating. For example, female moths release pheromones that attract males. Ants mark their trails with pheromones.

Most pheromones elicit a very specific, immediate, but transitory type of behavior. Others trigger hormonal activities that result in slow but longer-lasting responses. Still other pheromones may elicit both transitory and longer-lasting responses. An advantage to pheromone communication is that relatively little energy is needed to synthesize the simple, but distinctive, organic compounds involved. Members of the same species

have receptors that fit the molecular configuration of the pheromone; other species usually ignore it or do not detect it at all.

Pheromones are effective in the dark, can pass around obstacles, and last for several hours or longer. A major disadvantage of pheromone communication is that pheromones are transmitted slowly. Also, their information content is limited. However, some animals secrete several pheromones with different meanings.

Pheromones are important in attracting the opposite sex and in sex recognition in many species. Many social insects use these chemical signals to regulate reproduction. Humans have taken advantage of some sex-attractant pheromones to help control pests such as gypsy moths. They lure the males to traps baited with synthetic versions of female gypsy moth pheromones.

In honeybees, certain fatty acids are mixed with hydrocarbons from wax glands, and this mixture is transferred onto worker bees when they touch the comb. This mixture serves as a pheromone that identifies all the bees that belong to a particular hive. Should a bee from another hive attempt to enter, guard bees sting and may even kill the foreigner.

In vertebrates, pheromones affect sexual cycles and reproductive behavior, including choice of a mate. Pheromones may also play a role in defending territory. Among some mammals, an ovulating female (one physiologically ready to mate) releases pheromones as part of her vaginal secretion. When males detect these chemical odors, their sexual interest increases. When the odor of a male mouse is introduced among a group of females, the reproductive cycles of the female mice synchronize. In some species of mice, the odor of a strange male, a sign of high population density, causes a newly impregnated female to abort.

The extent to which humans respond to pheromones is the focus of considerable research. One interesting finding suggests that an unconsciously perceived body odor can synchronize the menstrual cycles of women who associate closely (e.g., college roommates or prison cell mates). Human steroids used in commercial fragrances such as perfumes may act as subtle signals that modulate mood and behavior.

As discussed in Chapter 43, mammals detect pheromones with specialized chemoreceptor cells that make up the **vomer nasal organ** in the epithelium of the nose. The vomer nasal sensory neurons signal the amygdala and hypothalamus, brain structures that regulate emotional responses and certain endocrine processes. When neurons of the vomer nasal system are damaged in virgin mice, they do not mate. Biologists have identified about 100 genes that code for pheromone receptors in the mouse and rat. These receptors initiate **signal transduction** pathways that involve G proteins.

Dominance hierarchies establish social status

In the spring, female paper wasps awaken from hibernation and begin to build a nest together. During the early course of construction, a series of squabbles among the females takes place in which the combatants bite one another's bodies or legs. Finally, one of the wasps emerges as dominant. After that, she is rarely challenged. This queen wasp spends more and more time tending the nest and less and less time out

foraging for herself. She takes the food she needs from the others as they return.

The queen then begins to take an interest in raising a family, her family. Because she is almost always in the nest, she can prevent other wasps from laying eggs in the brood cells by rushing at them, jaws agape. Because of her supreme dominance, the queen can bite any other wasp without serious risk of retaliation.

The other wasps of the nest are further organized into a **dominance hierarchy**, a ranking of social status in which each wasp has more status than the wasps that are lower in rank. Wasps lower in the hierarchy are subordinate to those above them, as follows:

queen → wasp A → wasp B → . . . wasp M

Once a dominance hierarchy is established, little or no time is wasted in fighting. When challenged, subordinate wasps communicate with submissive poses that inhibit the queen's aggressive behavior. Consequently, few or no colony members are lost through wounds sustained in fighting one another. This social organization ensures greater reproductive success for the colony.

In many species, males and females have separate dominance systems. For example, both female and male chimpanzees establish dominance hierarchies. Some females apparently become dominant through aggressive behavior, whereas others achieve high rank by virtue of their mother's status. Dominant females are more successful reproductively than those with lower social status. In many monogamous animals, especially birds, the female acquires the dominance status of her mate by virtue of their relationship and the male's willingness to defend her.

Like many fishes and some invertebrates, certain coral reef fishes (labrids) are capable of sex reversal. The largest, most dominant individual of a group is always male, and the remaining fish within his territory are all female. If the male dies or is removed, the most dominant female becomes the new male. Should any harm come to him, the next-ranking female undergoes sex reversal, takes charge, and protects the group territory. Other fishes exhibit the reverse behavior, in which the most dominant fish is always female. In such species size is less important for aggressive defense than for maximal egg production.

In establishing dominance, males may expend energy in posturing, roaring, leaping about, or sometimes fighting fiercely. These behaviors appear to be a test of male quality. The male with the greatest endurance will likely gain dominance and will have the greatest opportunity to mate and perpetuate his genes. In many animals, social dominance is a function of aggressiveness (FIG. 52-14). Tremendous energy is often needed for the fights engaged in by some birds and many mammals, including baboons, rams, and elephant seals. Establishing dominance is often strenuous and dangerous.

Sex hormones, particularly the male reproductive hormone testosterone, increase aggressiveness. The female hormone estrogen sometimes reduces dominance. Among chickens, the rooster is the most dominant. If a hen receives testosterone injections, her place in the dominance hierarchy shifts upward. When male rhesus monkeys are dominant,

Paul Brough/Science Source

Figure 52-14 Communicating dominance in social groups

This “sacred” baboon (*Papio hamadryas*) bares his teeth and screams in an unmistakable show of aggression. As in many social groups, such signals allow him to establish and maintain dominance.

their testosterone levels are much higher than when they have been defeated. Not only can testosterone increase dominance, but dominance may even increase testosterone production. It is not always easy to determine cause and effect. (Studies suggest that the effects of testosterone on human mood and behavior may be different from those in other vertebrates.)

Social status affects many organs and systems, including brain structure. For example, dominant male rats have more new neurons in the hippocampus than subordinate rats or controls.

Many animals defend a territory

Most animals have a **home range**, a geographic area they seldom leave (FIG. 52-15). Because the animal has the opportunity to become familiar with everything in that range, it has an advantage over its competitors, predators, and prey in negotiating the terrain and finding food. Some animals exhibit **territoriality**. They defend a *territory*, a portion of the home range, often against other individuals of their species and sometimes against individuals of other species. Many species are territorial for only part of the year, often during the breeding season, but others are territorial throughout the year. Territoriality has been positively correlated with the availability of needed resources that occur in small areas that can be defended.

Territoriality is easily studied in birds. Typically, the male chooses a territory at the beginning of the breeding season. This behavior results from high sex hormone concentrations in his blood. The males of adjacent territories fight until territorial boundaries become established. Generally, the dominance of a male is directly associated with how close he is to the center of his territory. When close to home, he acts like a lion, but when invading some other bird's territory, he may behave more like a lamb. Sometimes males respect a neutral line, an area between their territories in which neither is dominant.

Figure 52-15 Home range

Cape buffalo (*Syncerus caffer*) live in herds of several hundred animals. Each herd, such as this one photographed in the Serengeti, has a fairly constant home range. Buffalo protect herd members, especially calves, from potential predators.

Birds use songs to announce their territory and songs often substitute for fighting. Songs also announce to eligible females that a propertied male resides in the territory. Typically, male birds take up a conspicuous station, sing, and sometimes display striking patterns of coloration or aerial acrobatics to their neighbors, their rivals, and sometimes their mates.

The costs of territoriality include the time and energy expended in staking out and defending a territory and the risks involved in fighting for it. Benefits often include exclusive rights to food within the territory and greater reproductive success. The males of a lion pride father all the cubs born within that pride. Their ability to defend their territory from invasion by strange males ensures their reproductive success. Among many species, animals that fail to establish territories fail to reproduce. Territoriality also tends to reduce conflict among members of the same species and ensures efficient use of environmental resources by encouraging individuals to spread throughout a habitat.

Usually, territorial behavior is related to the specific life-style of the animal and to whatever aspect of its environment is most critical to its reproductive success. For instance, seabirds may range over hundreds of square kilometers of open water but exhibit territorial behavior only at crowded nesting sites on an island. The nesting sites are their scarcest resource and the one for which competition is keenest.

Some insect societies are highly organized

Social insects form elaborate societies. Characteristics of a highly organized society include cooperation and division of labor among animals of different sexes, age groups, or castes. An intricate system of communication reinforces the organization of the society. The members tend to remain together and to resist attempts by outsiders to enter the group.

By cooperation and division of labor, some insects construct elaborate nests and raise young by mass-production methods. Bees, ants, wasps, and termites form the most organized insect societies. (The first three of these all belong, not coincidentally, to the same order, Hymenoptera.) Insect societies are held together by a complex system of sign stimuli that are keyed to social interaction, and their behaviors tend to be quite rigid.

The social organization of honeybees has been studied more extensively than that of any other social insect. Instructions for the honeybee society are inherited and preprogrammed, and the size and structure of the bee's nervous system permit only a limited range of behavioral variation. These insects are not automata, however. Within its inherited limits, the complex bee society can respond with some flexibility to food and other stimuli in the environment.

A honeybee society generally consists of a single adult queen, up to 80,000 worker bees (all female), and at certain times, a few males called drones that fertilize newly developed queens. The queen, the only female in the hive capable of reproduction, deposits about 1000 fertilized eggs per day in the wax cells of a comb.

The composition of a bee society is generally controlled by a pheromone secreted by the queen. It inhibits the workers from raising a new queen and prevents development of ovaries in the workers (FIG. 52-16). If the queen dies or if the colony becomes so large that the inhibiting effect of the pheromone dissipates, the workers begin to feed some larvae special food that promotes their development into new queens.

Figure 52-16 Maintaining a complex social structure

Numerous worker honeybees surround their queen (center). Workers constantly lick secretions from the queen bee. These secretions, transmitted throughout the hive, suppress the activity of the workers' ovaries.

The queen bee stores sperm cells from previous matings in a seminal receptacle. If she releases sperm to fertilize an egg as it is laid, the resulting offspring is female; otherwise, it is male. Thus, males develop by parthenogenesis from unfertilized eggs and are haploid. Because a drone is haploid, each of his sperm cells has *all* his chromosomes; that is, meiosis does not occur during sperm production. The queen bee stores this sperm throughout her lifetime and uses it to produce worker bees.

The worker bees of a hive are more closely related to one another than would be sisters born of a diploid father. Indeed, they have up to three-fourths of their genes in common. (Assuming the queen bred with a single drone, they share half of the queen's chromosomes and all the drone's chromosomes.) As a consequence, they are more closely related to one another than they would be to their own offspring, if they could have any. (A worker bee's female offspring would have only half of its genes in common with its worker mother.) New queens are also their sisters. Worker bees are therefore more likely to pass on copies of their genes to the next generation by raising these individuals than they would if they were to produce their own offspring.

Division of labor among worker bees is mostly determined by age. The youngest worker bees serve as nurses that nourish larval bees. After about a week as nurse bees, workers begin to produce wax and build and maintain the wax cells. Older workers are foragers, bringing home nectar and pollen. Most worker bees die at the ripe old age of 42 days.

Bees have the most sophisticated mode of communication known among nonmammals. They perform a stereotyped series of body movements called a *dance*. The dance re-enacts, in miniature, the bee's flight to the food. When a honeybee scout locates a rich source of nectar, it apparently observes the angles among the food, hive, and the sun. The forager bee then communicates the direction and distance of the food source relative to the hive (FIG. 52-17). If the food supply is within about 52 m (about 55 yd), the scout performs a *round dance*, which generally excites the other bees and prompts them to fly short distances in all directions from the hive until they find the nectar. If the food is distant, however, the scout performs a *waggle dance*, which follows a figure-eight pattern.

In the 1940s, German zoologist Karl von Frisch pioneered studies in bee communication. He found that the waggle dance conveys information about both distance and direction. During the straight run part of the figure eight, the number and frequency of the waggles indicate the distance. The orientation of the movements indicates the direction of the food source in reference to the position of the sun. For example, if the bee dances straight up, the nectar is located directly toward the sun. If the bee dances

40 degrees to the left of the vertical surface of the comb, the nectar is located 40 degrees to the left of a line between the hive and the sun.

(a) **Round dance.** If the scout performs the round dance, it indicates the food source is close to the hive (within about 52 m).

(b) **Waggle dance.** If the scout performs the waggle dance, it indicates the food source is more distant from the hive. Distance is further indicated by how many abdominal waggles are performed in the straight part of the dance.

Source 1: Located toward the sun

Source 2: Located opposite the sun

Source 3: Located 40 degrees to the right of the sun

(c) **Direction coded in waggle dance.** If the scout waggles upward, it indicates the food source is toward the sun. If the scout waggles downward, it indicates the food source is in the opposite direction of the sun. If the scout waggles 40 degrees to the right, it indicates the food source is at a 40° angle to the right of the sun.

Figure 52-17 The honeybee dance

The forager bee typically performs the dance in the dark hive on the vertical surface of the comb. How, then, does its audience “see” the dance? Investigators have shown that the bee produces sounds as it dances. The auditory signals apparently communicate the position of the dancing bee.

52.6 Sexual Selection

LEARNING OBJECTIVE

- 10** Define *sexual selection* and describe different types of mating systems and approaches to parental care.

Sexual selection is a type of natural selection for successful mating. Animals vary in their ability to compete for mates. Individuals with some inherited advantage, such as males with large size, have a greater chance to mate and pass on their genes to the next generation. The beneficial trait becomes more common in the population over time. Thus, sexual selection results in the reproductive advantage that some individuals have over others of the same species and sex.

For a male, reproductive success depends on how many females he can impregnate. For a female, reproductive success depends on how many eggs she can produce during her reproductive lifetime, on the quality of the sperm that fertilize them, and on the survival of her offspring to reproductive age. Recall that an animal's reproductive success is a measure of its *direct fitness*. We can distinguish between *intrasexual selection* and *intersexual selection*.

Animals of the same sex compete for mates

In **intrasexual selection**, individuals of the same sex actively compete for mates. Typically, in such populations abundant males compete for a limited number of receptive females. Competition may take the form of physical combat. Among many species—for example, baboons and elephant seals—the largest male has the advantage.

Often, males establish dominance in more subtle ways than direct competition. Many males use elaborate ornamental displays to establish dominance. For example, the male deer

with the largest antlers may discourage his competitors. The male bird with the most dramatic plumage and brightest colors may have a psychological advantage over competing males.

Several studies confirm that males ranking higher in a dominance hierarchy mate more frequently than males that rank lower. However, exceptions demonstrate the complexity of reproductive behavior among some species. For example, among baboons with a definite dominance hierarchy, males lower in the hierarchy copulated with females as frequently as did males of higher status. Investigators observed, though, that dominant males copulated more frequently with females that were in *estrus*, their fertile period.

Animals select quality mates

Females frequently have the opportunity to select a sexual partner from among several males. In **intersexual selection**, females select their mates on the basis of some physical trait or some resource offered by the winning suitors. The physical trait typically indicates genetic quality or good health. In many species, the success of a male in dominance encounters with other males indicates his quality to the female, and she allows the victorious male to court her. Some lower ranking males develop alternative strategies for attracting females. For instance, a male may win a female's interest by protecting her baby, even though it is not his own.

Females of some species select their mates based on ornamental displays. A female fish may select the most brightly colored male. Female birds often select males with the showiest plumage and brightest colors, and female deer prefer males that display elaborate antlers. Expression of ornamental traits may give the female important information about the male's physical condition and ability to fight. The size of the antlers of red deer, for example, may indicate combat effectiveness as well as proper nutrition and good health. Female lions are attracted to males with thick, dark manes, an indicator of good nutrition and plenty of testosterone (which regulates growth of hair and melanin production). Thus, in some species, ornaments signal good health and good genes.

Among crickets and many other insect species, a courting male offers a gift of food to a prospective mate. Studies show that the larger or higher quality the food offering is, the better the chances the male will be accepted.

Among some species of insects, birds, and bats, males gather in a small display area called a **lek**, where they compete for females. When a receptive female appears, males may excitedly display themselves and compete for her attention. Among some species, the female selects a male based on his location in the lek rather than on his appearance. The dominant male may occupy a central position and be chosen by most of the females. The female selects a male, mates with him, and then leaves the lek. The male remains to woo other females.

Courtship rituals ensure that the male is indeed a male and is a member of the same species. Rituals provide the female further opportunity to evaluate him. In some species, courtship may also be necessary as a signal to trigger nest building or ovulation. Courtship rituals can last seconds, hours, or days and often involve a series of behavioral patterns (**FIG. 52-18**). The first

Sidney Bahr/Science Source

(b) Egrets (*Egretta rufescens*) performing a mating dance.

Figure 52-18 Courtship rituals

Elaborate courtship rituals help animals determine that a potential mate is of the same species and gives each animal a chance to evaluate the other as a potential mate.

display by the male releases a counter behavior by the female. Her response, in turn, releases additional male behavior, and so on until the pair is physiologically ready for copulation. Specific cues enable courtship rituals to function as reproductive isolating mechanisms among species (see Fig. 20-3).

An extreme courtship ritual has been described for red-back spiders, which are closely related to the black widow spider. During copulation, the small male spider positions himself above his larger mate's jaws. During 65% of mating acts, the finale is that the female eats her suitor. The apparent explanation for this behavior is that the risk-taking male is able to copulate for a longer period and thus fertilize more eggs than males that are not cannibalized. Also, the female is more likely to reject additional mates.

Sexual selection favors polygynous mating systems

In most species, males make little parental investment in their offspring apart from providing sperm. Males ensure reproductive success by impregnating many females, increasing the probability that their genes will be propagated in multiple offspring. Thus, sexual selection often favors **polygyny**, a mating system in which males fertilize the eggs of many females during a breeding season.

In the mating system known as **polyandry**, one female mates with several males. Benefits may include receiving gifts from several males or enlisting several males' help in caring for the young. Data collected at Jane Goodall's research center at Gombe National Park in Tanzania indicate that female chimpanzees practice polyandry. Females mate with males of their own group, but when they are most fertile, many females slip off to neighboring communities and copulate with less familiar males. Perhaps these sexual rendezvous protect against inbreeding.

Investigators also hypothesize that mating with many males provides insurance against infanticide. Males do not aggress against infants of mothers with which they have copulated. Studies indicate that females with multiple mates are more fertile and produce more offspring than those without multiple mates.

Polyandry and polygyny sometimes occur in the same species. After mating, a female giant water bug attaches a clutch of eggs to her mate's back (FIG. 52-19a). He cares for the eggs until they hatch. She then may mate with a different male and glue the new clutch of eggs to his back. However, if the male has more space for eggs, he may mate with another female.

Apparently, in most species it is not certain which male fathered the offspring. However, raising some other male's offspring is a genetic disadvantage, so males of some species may compromise mate-chasing behavior in favor of **mate guarding**. The male guards his partner after copulation to ensure that she does not copulate with another male.

Mate-guarding behavior is likely to occur when the female is receptive and has eggs that might be fertilized by another male. For example, dominant male African elephants guard a female only during the phase of estrus when she is most likely to be fertile. Before that time, or later in estrus after mating has already occurred, younger male elephants of lesser social status can copulate with the female. A high cost of mate guarding is the loss of opportunity for a dominant male to mate with other females.

Sexual selection favors males that inseminate many females and produce many offspring. Perhaps for this reason, **monogamy**, a mating system in which a male mates with only one female during a breeding season, is not common. Less than 10% of mammals are monogamous.

Researchers long thought that monogamy was common among birds because many species form **pair bonds**, which are stable relationships that ensure cooperative behavior in mating and the rearing of the young. However, genetic evidence shows

Figure 52-19 Caring for the young

Parental investment in offspring increases the probability that the young will survive.

that some offspring are fathered by males other than the one caring for them. For example, DNA tests show that among eastern bluebirds, 15% to 20% of the chicks are fathered by other males. The extra-pair male contributes new genes. The female then produces offspring with greater genetic variability, increasing the chance that at least some of her offspring will survive. Some researchers distinguish between *sexual monogamy* and *social monogamy*, in which animals form a pair bond.

Monogamy does occur in some species, typically when males are needed to protect and feed the young. For example, the California mouse is sexually as well as socially

McMurray Photography

(d) Female cheetah (*Acinonyx jubatus*) stands watch as her cubs eat the Thompson's gazelle she has hunted and killed for them.

monogamous. The offspring need their parents' body heat to survive, and the parents take turns keeping them warm.

Some animals care for their young

Parental investment is the contribution that each parent makes in producing and rearing offspring. The benefit of parental investment is the greater probability that each offspring will survive. Despite this, most animals do not invest time and energy in caring for their offspring because the costs of parenting are high. For example, an animal busy feeding and protecting offspring might produce fewer additional offspring. There are also risks in protecting the young from predators.

Natural selection has favored parental care in species in which the female produces few young or reproduces only once during a breeding season. Parental care is an important part of successful reproduction in some invertebrates, including some cnidarians (jellyfish), rotifers, mollusks, and arthropods (crustaceans, insects, spiders, and scorpions), and is a common practice among vertebrates (FIG. 52-19b–d).

Females of many vertebrate species produce relatively few, large eggs. Because of the time and energy invested in producing eggs and carrying the developing embryo, the female has

more to lose than the male if the young do not develop. Thus, females are more likely than males to brood eggs and young, and usually females invest more in parental care. Parental care is especially skewed toward the female in mammals because females provide milk to nourish their young. Investing time and effort in care of the young is usually less advantageous to a male than to a female (assuming that the female can handle the job by herself) because time spent in parenting is time lost from inseminating other females.

In some situations a male benefits by helping rear his own young or even those of a genetic relative. Receptive females may be scarce, breeding territories may be difficult to establish or guard, and gathering sufficient food may require more effort than one parent can provide. In some habitats the young need protection against predators or cannibalistic males of the same species. Among wolves and many other carnivores, for example, males defend the young and the food supply.

Among many species of fish, the male cares for the young. Apparently, parenting costs to the males are less than they would be for the females. A male fish must have a territory to attract a female. While guarding his territory, the male guards the fertilized eggs as well. Having eggs also appears to make the male more attractive to potential mates. In contrast, when a female is caring for her eggs or young, she is not able to feed optimally. As a result, her body size is smaller, and her fertility is reduced.

Behavioral ecologist Bryan D. Neff of the University of Western Ontario showed that male bluegill sunfish (*Lepomis macrochirus*) adjust their level of caregiving according to their degree of certainty that the offspring are indeed their own. Adult males, called parentals, defend a nest, attract females, and care for the eggs and newly hatched offspring. Some males, called *sneaker males* (or cuckolders), sneak into nests and fertilize eggs during spawning. Other sneaker males have developed in a way that gives them characteristics of females. The parental male is tricked into regarding the sneaker male as another female, allowing it access to the eggs (FIG. 52-20).

Neff performed a series of experiments in which he placed sneaker males in transparent containers so that they could not fertilize eggs but the parentals could see them. In response, parentals reduced their level of protecting the eggs (FIG. 52-21). However, after the eggs hatched, the parentals increased their level of care. Apparently, olfactory cues indicated that these young fish were indeed the offspring of the parental caring for them. (They smelled right.)

In a second experiment, Neff exchanged about one-third of the eggs between two nests. Parentals continued to protect the eggs, but after the eggs hatched, parentals decreased their level of care. This investigator showed that parentals responded to olfactory cues. At least some of their offspring did not smell right. (The odor may be produced by the offspring's urine.) Neff suggested that an animal learns its own odor (or appearance) and forms a template of what its relatives should smell (or look) like. If they don't match up closely enough, they may be rejected.

Figure 52-20 Deception in mating

A large parental (adult male) bluegill sunfish (*Lepomis macrochirus*) courts a female (center). Another male, impersonating a female, swims close to the female (right). The parental is not aware that the sneaker is a rival male. In about 20% of spawnings, a sneaker fertilizes some of the eggs and then swims away.

CHECKPOINT 52.6

- What is sexual selection? What are some factors that influence mate choice?
- Under what conditions does sexual selection favor polygynous (or polyandrous) mating systems? Why is monogamy uncommon?
- What are some benefits of courtship rituals?
- **CONNECT** Why do more females than males invest in caring for their offspring? Explain in terms of costs, benefits, and fitness.

52.7 Helping Behavior

LEARNING OBJECTIVE

- 11** Relate the concepts of inclusive fitness and kin selection to altruism.

Does a male bluegill sunfish adjust his level of caregiving if he perceives that he is not the genetic parent of the eggs or offspring that he is guarding?

HYPOTHESIS: Behavioral ecologist Bryan D. Neff hypothesized that male bluegill sunfish adjust the level of their parental care according to their level of perceived paternity.

EXPERIMENTS: Neff manipulated visual and olfactory cues.

In **Experiment 1**, Neff manipulated sneaker males. He placed two transparent containers with sneaker males near the nests of 34 parentals (adult males) and left them there during spawning. Empty containers were placed around 20 control nests. After the fish spawned, a potential egg predator (a pumpkinseed sunfish in a clear plastic container) was presented, and the parental's defensive behavior was observed and quantified for both experimental and control groups.

In **Experiment 2**, the investigator removed one-third of the eggs from the nests of 20 parentals and replaced them with eggs from other nests. Sham egg swaps were carried out on eggs of 15 control parentals. Parental defensive behavior was observed before and after the eggs hatched.

RESULTS:

Experiment 1: As indicated on the y-axis, which measures level of parental care, parentals reduced their level of guarding the eggs. Eight of the males in the experimental group abandoned their nests, and egg defense was significantly lower in this group compared with that in the control group. However, after eggs hatched, there was little difference in parental care of the young between the two groups.

Experiment 2: During the egg phase, there was little difference in level of parental care between experimental and control groups. However, after eggs hatched, the experimental parentals significantly decreased their level of guarding the nest.

CONCLUSION: Male bluegill sunfish adjust their level of parental care according to their level of perceived paternity.

In **Experiment 1**, parentals provided less care when they perceived that the eggs may have been fertilized by sneaker males. After the eggs hatched, olfactory cues indicated that the offspring were indeed their own, and their level of care increased.

In **Experiment 2**, parentals cared for the eggs even though some had been swapped. However, after they hatched, olfactory cues from the offspring indicated that they were not the parental's own offspring. The level of parental care decreased significantly.

SOURCE: B.D. Neff, *Nature*, Vol. 422 (April 17, 2003): 716–719.

Figure 52-21 Decisions about parental care

PREDICT Imagine the investigator had temporarily blinded the male sunfish in Experiment 1. How might the results have been different?

Among wild turkeys and many other species, subordinate males help dominant males attract a mate, but the subordinate males do not reproduce. If an animal's principal evolutionary mandate is to perpetuate its genes, we must wonder why some animals spend time and energy in helping others.

Altruistic behavior can be explained by inclusive fitness

In a type of cooperative behavior known as **altruistic behavior**, one individual behaves in a way that seems to benefit others rather than itself, with no potential payoff. In fact, the helper experiences a fitness cost, whereas the recipient of the altruistic behavior benefits. How could true altruistic behavior be adaptive if the animal's response decreases its reproductive success relative to individuals that do not exhibit the altruistic behavior? In 1964, British evolutionary biologist William D. Hamilton offered a plausible explanation. He suggested that evolution does not distinguish between genes transmitted directly from parent to offspring and those transmitted indirectly through close relatives.

According to Hamilton, natural selection favors animals that help a relative because the relative's offspring carries some of the helper's alleles. **Inclusive fitness** is the sum of direct fitness (which can be measured by the number of alleles an animal perpetuates in its offspring) plus indirect fitness (the alleles it helps perpetuate in the offspring of its kin).

We can measure the potential genetic gain from helping relatives by the *coefficient of relatedness*, the probability that two individuals inherit the same uncommon allele from a recent common ancestor. The coefficient of relatedness for two animals that are not related is 0, whereas between a parent and its offspring this coefficient is 0.5, indicating that half of their genes are the same. The coefficient of relatedness for siblings is also 0.5; for first cousins, it is 0.125. The higher the coefficient of relatedness, the more likely an animal will help a relative.

Hamilton developed a mathematical model to show how an allele that promotes altruistic behavior can increase in frequency in a population. According to *Hamilton's rule*, an altruistic act is adaptive if (1) its indirect fitness benefits are high for the animals that profit, (2) the recipients are close relatives of the altruist, and (3) the direct fitness cost to the altruistic animal is low.

Behavioral ecologists have made DNA fingerprints of lions in the Serengeti National Park and in the Ngorongoro Crater (both in Tanzania). Their findings confirm that lion brothers that cooperate in prides have a greater probability of perpetuating their genes than those that go off on their own. This finding is true even if the lion perpetuates his genes only by proxy, through his brother. **Kin selection**, also called *indirect selection*, is a form of natural selection that increases inclusive fitness through the breeding success of close relatives.

The bee society provides an interesting example of kin selection. Recall that worker bees do not reproduce, but they do nourish larval bees. The worker bees have up to three-fourths of their genes in common with the larval bees. For this reason, worker bees are more likely to perpetuate their genes by raising larval bees than they would by producing their own offspring.

Some birds (such as Florida scrub jays) engage in a type of *cooperative breeding* in which non-reproducing individuals aid in rearing the young. Nests tended by these additional helpers as well as parents produce more young than do nests with the same number of eggs overseen only by parents. The non-reproducing helpers are close relatives that increase their own biological success by ensuring the successful, although indirect, perpetuation of their genes. Helpers may be prevented from producing their own offspring by limiting factors such as a shortage of mates or territories.

Helping behavior may have alternative explanations

Some behavioral ecologists are questioning the role of kin selection in helping behavior. One of the time-honored examples of kin selection has been sentinel behavior, keeping watch for predators and warning other members of the group when danger threatens. Until recently, biologists thought that sentinels were at greater risk for predation than other members of that group, yet selflessly engaged in risky behavior that benefited their relatives. This explanation appears valid for some species, including prairie dogs and ground squirrels. However, some studies suggest an opposing hypothesis for guarding behavior in other species.

U.S. biologist Peter A. Bednekoff developed a model to explain how guarding could result from selfish behavior. Bednekoff observed that for some species sentinels are not at higher risk than others in their group. In fact, the opposite may be true, and sentinels may actually have an advantage. By detecting predators first, the sentinels can escape more rapidly than others in the group.

Studies of sentinel behavior in the African mongoose, commonly known as the meerkat, support Bednekoff's model (**FIG. 52-22**). During 2000 hours of researcher observation, no sentinel was killed. In fact, investigators concluded that guarding is a selfish behavior in meerkat populations because sentinels were able to escape quickly into their nearby burrows. This research is an important reminder that it is risky for biologists to generalize the meanings of complex social behavior from one species to another. Many explanations are possible. Helpers often derive direct benefits in safety and eventual reproductive success. For example, among some species, younger animals that help are permitted to remain in the social group and derive the benefits of group protection. These helpers are also positioned to take over territories and mates when older members of the group die.

Some animals help nonrelatives

Occasionally, an animal helps a nonrelative in a fight, grooms it, or even shares food. Evolutionary biologist Robert L. Trivers of Rutgers University explained this behavior in 1971 with his hypothesis of **reciprocal altruism**. According to this hypothesis, one animal helps a nonrelative with no immediate benefit, but at some later time the animal that was helped repays the debt. In this way, the original helper experiences a net fitness benefit. A vampire bat that has just fed regurgitates blood for hungry bats that share the roost. If a bat does not share blood with a neighbor that has fed it in the past, the "cheater" will probably not be helped in the future.

Martin Harvey/Getty Images

Figure 52-22 Sentinel behavior in the meerkat (*Suricata suricatta*), also known as the African mongoose

Studies of sentinel behavior in meerkats suggest that meerkat sentinels are not being altruistic and their behavior is not about kin selection. In fact, guarding may actually be a selfish behavior, because when danger threatens, sentinels can quickly escape into the burrow.

CHECKPOINT 52.7

- **CONNECT** How does kin selection explain the evolution of altruistic behavior?
- **PREDICT** How might an animal benefit by helping a nonrelative?

52.8 Culture in Vertebrate Societies

LEARNING OBJECTIVE

- 12** Contrast a vertebrate society with a society of social insects, give examples of transmission of culture, and briefly describe sociobiology.

Vertebrate societies typically have nothing comparable to the physically and behaviorally specialized castes of honeybees or ants. An exception is the naked mole rat of southern Africa, a rodent that has a social structure closely resembling that of the social insects. Although most vertebrate societies seem simpler than insect societies, they are also more flexible. Vertebrate societies share a great range and plasticity of potential behaviors and can effectively modify behavior to meet environmental challenges.

Some vertebrates transmit culture

The behavioral plasticity of vertebrates makes possible the transmission of culture in some bird and mammal species. **Culture** is behavior common to a population, learned from other members of the group, and transmitted from one generation to another. Culture is not inherited. It is maintained by **social learning**, such as through observing others and imitating them or by teaching.

About 17 behaviors that may be considered cultural have been described among cetaceans (whales, dolphins, porpoises). For example, female orcas teach their offspring to hunt seals according to the custom of their particular group. Orcas also have local dialects that have been documented for at least six generations, suggesting that they are passed on from parent to offspring. Separate dialects are maintained even when various populations of orcas interact socially.

Biologists have reported that humpback whales learn new strategies for feeding by observing one another. Bottlenose dolphins are well known for their ability to learn by imitation. Behavioral ecologists have documented foraging practices that appear to be cultural, that is, transmitted by social learning.

Teaching is an efficient form of social learning. If adult animals can teach younger ones, critical information can be rapidly transferred from one generation to the next (**FIG. 52-23**). University of Cambridge researchers Alex Thornton and Katherine McAuliffe reported that helper meerkats teach pups skills for capturing prey. Meerkats feed on a variety of animals, many of which are difficult to subdue. Some, such as scorpions, are potentially dangerous. Young meerkat pups cannot find and capture their own prey. Instead, they emit begging calls that induce helpers to feed them. Helpers monitor and nudge the pups to handle the prey efficiently. As they grow older, the pups' begging calls change. In response, helpers modify their teaching, giving the pups the opportunity to practice a greater range of skills. The helpers gradually introduce the pups to live prey.

Studies of chimpanzee populations demonstrate that some groups develop local customs and teach them to their offspring. Using data provided by researchers at seven chimpanzee research sites, animal behaviorists identified 39 chimpanzee behaviors that they considered cultural variations. These behaviors included various ways of using tools, courtship rituals, and grooming techniques. Each of these local customs was learned from other chimpanzees in the population, and customs varied among different populations. For example, chimpanzees on the western side of the Sassandra-N'Zo River use stone hammers to crack coula nuts. Researchers have photographed mother chimpanzees

Figure 52-23 Mother orca and her calf breaching

As this mother orca and her calf breach, they leap out of the water, exposing two-thirds or more of their bodies, and then land on their sides. Orcas educate and discipline their calves.

teaching this behavior to their offspring. Just a few miles away on the eastern side of the river, chimpanzees do not crack nuts, even though they are available.

When a chimp migrates and joins a new population, it can transmit knowledge learned in its previous culture. In this way, cracking nuts and other customs spread from one population to another. An example of cultural transmission has been observed in a chimp community at Gombe. (Anthropologist Jane Goodall has studied the chimps there since 1960.) An adult female chimp that joined the Gombe chimp community in the early 1990s had apparently learned to use tools to fish out carpenter ants in her former community. Some of the young chimps of her new community observed this behavior and learned how to insert sticks into holes to fish out ants.

As researchers continue to study cultural variation among chimpanzee populations, learning ever more about our closest relatives, it is important to remember that the capacity to learn such behaviors is the product of natural selection. The behaviors that are maintained are adaptive for these animals

in their environment. Studying culture in nonhuman primates may provide insights into the evolutionary origins of human culture. Human society is based to a great extent on the symbolic transmission of culture through spoken and written language.

Sociobiology explains human social behavior in terms of adaptation

Sociobiology focuses on the evolution of social behavior through natural selection. In his landmark book, *Sociobiology: The New Synthesis*, published in 1975, Edward O. Wilson combined principles of population genetics, evolution, and animal behavior to present a comprehensive view of the evolution of social behavior. Like Darwin and many other biologists of the past, Wilson suggested that human behavior can be studied in evolutionary terms. Many of the concepts discussed in this chapter, such as paternal investment in care of the young, are based on contributions made by Wilson and other sociobiologists. Wilson's work greatly influenced the development of behavioral ecology, evolutionary psychology, and evolutionary anthropology.

Sociobiology has been controversial, at least in part because of its application to human behavior and the possible ethical implications of such application. Some critics have complained that according to sociobiology human behavior may not be flexible enough to permit substantial improvements in the quality of our social lives. Sociobiologists, however, agree with their critics that human behavior *is* flexible. At least some of the debate focuses on the *degree* to which human behavior is genetically determined and the extent to which it can be modified.

As sociobiologists acknowledge, people can, through culture, change their way of life far more profoundly in a few years than could a hive of bees or a troop of baboons in hundreds of generations of genetic evolution. This capacity to make changes is indeed genetically determined, and it is a great gift. How we use it and what we accomplish with it are not a gift but, rather, a responsibility on which our own well-being and the survival of other species depend.

CHECKPOINT 52.8

- **CONNECT** How are vertebrate societies different from those of social insects?
- What are some examples of culture?
- According to sociobiologists, what determines social behavior?

Summary: Focus on Learning Objectives

52.1 Behavior and Adaptation (page 1125)

1 Distinguish between proximate and ultimate causes of behavior and apply the concepts of ultimate cause and cost–benefit analysis to decide whether a particular behavior is adaptive.

- **Behavior** is what an animal does and how it does it, usually in response to stimuli in its environment. **Proximate causes** of behavior are immediate causes, such as genetic, developmental, and physiological processes that permit the animal to carry out a specific behavior. Proximate causes answer *how* questions. **Ultimate causes** are the evolutionary explanations for *why* a certain behavior occurs.
- We can use **cost–benefit analysis** to determine whether a behavior is adaptive. Benefits contribute to **direct fitness**, the animal's reproductive success measured by the number of viable offspring it produces. If benefits outweigh costs, the behavior is adaptive.

2 Describe the interactions of heredity, environment, and maturation in animal behavior.

- Behavior results from the interaction of genes (**innate behavior**) and environmental factors. The capacity for behavior is inherited, but behavior is modified in response to environmental experience.
- An organism must be mature—physiologically ready to produce a given behavior—before it can perform that pattern of behavior. Walking and many other behaviors that we view as automatic are **motor programs**, coordinated sequences of muscle actions.
- A **behavioral pattern** is an automatic behavior that, once activated by a simple sensory stimulus, continues to completion regardless of sensory feedback. A behavioral pattern can be triggered by a specific unlearned **sign stimulus**, or *releaser*.

52.2 Learning: Changing Behavior as a Result of Experience (page 1127)

3 Discuss the adaptive significance of habituation, imprinting, classical conditioning, operant conditioning, and cognition.

- **Learning** is a change of behavior that results from experience. **Habituation** is a type of learning in which an animal learns to ignore a repeated, irrelevant stimulus so that it can focus on finding food and carrying out other life activities.
- **Imprinting** establishes a parent–offspring bond during a *critical period* early in development, ensuring that the offspring recognizes its mother.
- In **classical conditioning**, an association is formed between some normal body function and a new stimulus. This type of learning allows an animal to make an association between two stimuli.
- In **operant conditioning**, an animal learns a behavior so as to receive positive reinforcement or to avoid punishment. This type of learning is important in many natural situations; for example, young herring gulls perfect their pecking behavior so as to obtain food.
- **Cognition** is the process of gaining and using knowledge; it includes knowing, thinking, processing information, learning, reasoning, and awareness of thoughts, perceptions, and self. Cognition allows some animals to adapt

past experiences to solve new problems that may involve different stimuli.

52.3 Behavioral Responses to Environmental Stimuli (page 1131)

4 Give examples of biological rhythms and describe some of the physiological mechanisms responsible for them.

- It is adaptive for an organism's metabolic processes and behavior to be synchronized with cyclical changes in the environment. In many species physiological processes and activities follow **circadian rhythms**, which are daily cycles of activity.
- **Diurnal animals** are most active during the day; **nocturnal animals**, at night; and **crepuscular animals**, at dawn or dusk. Some biological rhythms—for example, the changes in tides due to changes in the phase of the moon—reflect the *lunar cycle*.
- Many biological rhythms are regulated by internal timing mechanisms that serve as **biological clocks**. In mammals the master clock is located in the **suprachiasmatic nucleus (SCN)** in the hypothalamus.

5 Analyze costs and benefits of migrations and distinguish between directional orientation and navigation.

- **Migration** is periodic long-distance travel from one location to another. Proximate causes of migration include physiological responses that are triggered by environmental changes. Ultimate causes of migration include the benefit of moving away from an area that seasonally becomes too cold, dry, or depleted of food to a more hospitable area. Costs of migration include time, energy, and greater risk of predation.
- **Directional orientation** is travel in a specific direction and requires **compass sense**, a sense of direction. Many migrating animals use the sun to orient themselves.
- **Navigation** requires both compass sense and **map sense**, an awareness of location. Birds that navigate at night use the stars as guides. Birds and many other animals also use Earth's magnetic field to navigate.

52.4 Foraging Behavior (page 1133)

6 Define *optimal foraging behavior* and explain how it is adaptive.

- **Optimal foraging**, the most efficient strategy for an animal to get food, can enhance reproductive success.

52.5 Costs and Benefits of Social Behavior (page 1134)

7 Analyze social behavior in terms of costs and benefits, and compare different types of social groups, including societies of social insects.

- **Social behavior** is the interaction of two or more animals, usually of the same species. An organized **society** is an actively cooperating group of individuals belonging to the same species and often closely related. In some species social organization ensures greater reproductive success than do noncooperative arrangements.
- Many animal societies are characterized by a means of communication, cooperation, division of labor, and a tendency to stay together. Benefits include cooperative foraging

or hunting and defense from predators. Costs include increased competition for food and habitats and increased risks of attracting predators and transmitting disease.

8 Describe common modes of animal communication, including signaling by pheromones.

- Animal *communication* involves the exchange of mutually recognizable signals, which can be electrical, tactile, visual, auditory, or chemical. **Pheromones** are chemical signals that convey information between members of a species.

9 Compare the costs and benefits of dominance hierarchies and of territoriality.

- A **dominance hierarchy** is a ranking of status within a group in which more dominant members are accorded benefits (such as food or mates) by subordinates. Establishing dominance often, but not always, involves aggressive behavior. Social ranking reduces costly physical fights.
- Animals often inhabit a **home range**, a geographic area that they seldom leave but do not necessarily defend. A defended area within a home range is called a *territory*, and the defensive behavior is territoriality. Costs of **territoriality** include time and energy expended in staking out and defending a territory and risks in fighting for it. Benefits include rights to food in the territory and reduction in conflict among members of a population.

52.6 Sexual Selection (page 1140)

10 Define sexual selection and describe different types of mating systems and approaches to parental care.

- **Sexual selection**, a type of natural selection, occurs when individuals vary in their ability to compete for mates. Individuals with reproductive advantages are selected over others of the same sex and species. In **intrasexual selection**, animals of the same sex actively compete for mates.
- In **intersexual selection**, females may choose their mates based on dominance, gifts, ornaments, or courtship displays. Males of some species gather in a **lek**, a small display area where they compete for females. **Courtship rituals** ensure that the male is a member of the same species and permit the female to assess the quality of the male.
- Sexual selection often favors **polygyny**, a mating system in which a male mates with many females. In **polyandry** a female mates with several males. **Monogamy**, mating with a single partner during a breeding season, is less common. Among many species, males engage in **mate guarding**, especially when the female is most fertile, to prevent other males from fertilizing her eggs.
- A **pair bond** is a stable relationship between a male and a female that may involve cooperative behavior in mating and in rearing the young. **Parental investment** in care of

eggs and offspring increases the probability that offspring will survive. A high investment in parenting is typically less advantageous to the male than to the female.

McMurray Photography

52.7 Helping Behavior (page 1143)

11 Relate the concepts of inclusive fitness and kin selection to altruism.

- **Altruism** is a type of cooperative behavior in which one individual appears to behave in a way that benefits others rather than itself. **Inclusive fitness** is the sum of an individual's direct fitness and indirect fitness (number of offspring of kin). This concept suggests that natural selection favors animals that help a relative because it is an indirect way to perpetuate some of the helper's own alleles.
- According to *Hamilton's rule*, an altruistic act is adaptive if its indirect fitness benefits are high for the animals that are helped, if the recipients are close relatives of the altruist, and if the direct fitness cost to the altruist is low.
- **Kin selection** is a type of natural selection that increases inclusive fitness through successful reproduction of close relatives. Some types of cooperative behavior may increase the direct fitness of the helper.
- In a type of cooperative behavior known as **reciprocal altruism**, the helper does not immediately benefit but is helped later by the animal it helped.

52.8 Culture in Vertebrate Societies (page 1146)

12 Contrast a vertebrate society with a society of social insects, give examples of transmission of culture, and briefly describe sociobiology.

- Compared with insect societies, vertebrate societies are more flexible and the role of the individual less narrowly defined. Some bird and mammal species develop **culture**, learned behavior common to a population that is transmitted from one generation to the next. Symbolic transmission of culture is important in human societies.
- **Sociobiology** focuses on the evolution of social behavior through natural selection.

Test Your Understanding

Know and Comprehend

1. The responses of an organism to signals from its environment are its (a) behavior (b) culture (c) ultimate behavior (d) releasers (e) motor programs
2. A behavioral pattern is elicited by (a) a motor program (b) a sign stimulus (c) an imprint (d) a, b, and c (e) b and c
3. A form of learning in which an animal forms a strong attachment to a moving object (usually its parent) within a few hours of birth is (a) classical conditioning (b) operant conditioning (c) imprinting (d) insight learning (e) parental investment

4. Both compass sense and map sense are necessary for (a) navigation (b) migration (c) directional orientation (d) both navigation and migration (e) the action of biological clocks
5. In optimal foraging (a) animals always hunt in social groups (b) an animal obtains food in the most efficient way (c) animals can rarely afford to be selective (d) groups of five to seven animals are most successful (e) animals are typically most successful when they hunt alone
6. Chemical signals that convey information among members of a species are (a) pheromones (b) hormones (c) neurotransmitters (d) leks (e) neuropeptides
7. The benefits of territoriality include (a) right to defend a home range (b) higher potential for monogamy (c) energy investment in staking out and defending the area (d) increased reproductive success (e) pair bonding
8. Sexual selection (a) occurs mainly among animals that practice polyandry (b) occurs when animals are very similar in their ability to compete for mates (c) results in animals that have lower direct fitness (d) occurs mainly among animals that practice polygyny (e) is a form of natural selection
9. In most species mate choice is least likely influenced by (a) ornamental displays such as antlers (b) fidelity of the male (c) gifts (d) courtship behavior (e) dominance
10. Behavior that appears to have no payoff—that is, an individual appears to act to benefit others rather than itself—is known as (a) mutualism (b) helping behavior (c) reciprocal altruism (d) inclusive fitness (e) altruism
11. Kin selection (a) increases inclusive fitness through the breeding success of close relatives (b) is a way of perpetuating genes of nonrelatives (c) accounts for some forms of migration (d) typically involves mate guarding (e) involves ornamental displays and use of a lek
12. Culture (a) is common among invertebrate groups (b) does not vary within the same species (c) is behavior learned from other members of the group and shared by members of a population (d) has a strong genetic component in primates (e) is a shared derived character of humans

Apply and Analyze

13. Behavioral ecologists have demonstrated that young tiger salamanders can become cannibals and devour other salamanders. Investigators observed that the cannibal salamanders preferred eating unrelated salamanders over their own cousins and preferred eating cousins over their siblings. Explain this behavior based on what you have learned in this chapter.

Evaluate and Synthesize

14. **INTERPRET DATA** Look at the two graphs in Figure 52-21. In which experiment did the parentals in the experimental group guard the eggs more closely? In which experiment did the experimental parentals guard the young more closely? Account for these differences.
15. **INTERPRET DATA** Look at the diagram (Fig. 52-11) and identify the groups most likely to be hungry at the end of the day's hunt during times of prey scarcity. Develop a hypothesis to explain why these groups hunt as they do.
16. How is the society of a social insect different from human society? What are some similarities between the transmission of information by heredity and by culture? What are some differences?
17. **EVOLUTION LINK** What might be the adaptive value of sea turtle migration?
18. **SCIENCE, TECHNOLOGY, AND SOCIETY** Consider how the adaptive value of sea turtle migration has changed if, as a result of human activities, migration now puts sea turtles at greater risk than if they restricted their habitat to a single location. Discuss the possible evolutionary mechanisms by which the behavior of these species may (or may not) adapt to these environmental pressures. What conservation efforts should we take to increase the probability of successful migration?

53 Introduction to Ecology: Population Ecology

The science of **ecology** is the study of how living organisms and the physical environment interact in an immense and complicated web of relationships. Biologists call the interactions among organisms **biotic factors** and those between organisms and their nonliving, physical environment **abiotic factors**. Abiotic factors include precipitation, temperature, pH, wind, and chemical nutrients. Ecologists formulate hypotheses to explain such phenomena as the distribution and abundance of life, the ecological roles of specific species, the interactions among species in communities, and the importance of ecosystems in maintaining the health of the biosphere. They then test these hypotheses.

The focus of ecology can be local or global, specific or generalized, depending on what questions the scientist is asking and trying to answer. Ecology is the broadest field in biology, with explicit links to evolution and every other biological discipline. It includes studies on transfer of information among organisms and analyses of the transfer of energy for life. Its universality encompasses subjects that are not traditionally part of biology. Earth science, geology, chemistry, oceanography, climatology, and meteorology are extremely important to ecology, especially when ecologists examine the abiotic environment of planet Earth. Because humans are part of Earth's web of life, all our activities, including economics and politics, have profound ecological implications. *Environmental science*, a scientific discipline with ties to ecology, focuses on how humans interact with the environment.

As you learned in Chapter 1, most ecologists are interested in the levels of biological organization including and above the level of the individual organism: population, community, ecosystem, landscape, and biosphere. Each level has its own characteristic composition, structure, and functioning.

An individual belongs to a **population**, a group consisting of members of the same species that live together in a prescribed area

KEY CONCEPTS

- 53.1** A population can be described in terms of its density, dispersion, birth and death rates, growth rate, survivorship, and age structure.
- 53.2** Changes in population size are caused by natality, mortality, immigration, and emigration.
- 53.3** Population size may be influenced by density-dependent factors and density-independent factors.
- 53.4** Life history traits of a population are adaptations that affect the ability of individuals to survive and reproduce.
- 53.5** A metapopulation consists of two or more local populations with dispersal occurring among them.
- 53.6** Human population structure differs among countries in ways that are primarily related to differences in level of development.

PHOTO: A population of daffodils. These wild poet's daffodils (*Narcissus poeticus*) are blooming in an alpine meadow in Switzerland. Frank Lukasseck/Getty Images

at the same time. The boundaries of the area are defined by the ecologist performing a particular study. A population ecologist might study a population of microorganisms, animals, or plants, like the poet's daffodils in the photograph, to see how individuals within it live and interact with one another, with other species in their community, and with their physical environment.

In this chapter we begin our study of ecological principles by focusing on the study of populations as functioning systems and end with a discussion of the human population. Subsequent chapters examine the interactions among different populations within communities (Chapter 54), the dynamic exchanges between communities and their physical environments (Chapter 55), the characteristics of Earth's major biological ecosystems (Chapter 56), and biological diversity and conservation biology (Chapter 57).

53.1 Features of Populations

LEARNING OBJECTIVE

- 1 Define *population density* and *dispersion*, and describe the main types of population dispersion.

Populations exhibit characteristics distinctive from those of the individuals of which they are composed. Some features discussed in this chapter that characterize populations are population density, population dispersion, birth and death rates, growth rates, survivorship, and age structure.

Although communities consist of all the populations of all the different species that live together within an area, populations have properties that communities lack. Populations, for example, share a common gene pool (see Chapter 19). Consequently, natural selection can cause changes in allele frequencies in populations. As a result, allele frequency changes resulting from natural selection occur in populations. Natural selection therefore acts directly to produce adaptive changes in populations and only indirectly affects the community level.

Population ecology considers both the number of individuals of a particular species that are found in an area and the dynamics of the population. **Population dynamics** is the study of changes in populations: how and why those numbers increase or decrease over time. Population ecologists try to determine the processes common to all populations. They study how a population interacts with its environment, such as how individuals in a population compete for food or other resources and how predation, disease, and other environmental pressures affect the population. Population growth, whether of bacteria, maples, or giraffes, cannot increase indefinitely because of such environmental pressures.

Additional aspects of populations that interest biologists are their reproductive success or failure (extinction), their evolution, their genetics, and the way they affect the normal functioning of communities and ecosystems. Biologists in applied disciplines, such as forestry, agronomy (crop science), and wildlife management, must understand population ecology to manage populations of economic importance, such as forests, field crops, game animals, or fishes. Understanding the population dynamics of endangered and threatened

species plays a key role in efforts to prevent their slide to extinction. Knowledge of population ecology helps in efforts to prevent the increase of pest populations to levels that cause significant economic or health effects.

Density and dispersion are important features of populations

The concept of population size is meaningful only when the boundaries of that population are defined. Consider, for example, the difference between 1000 mice in 100 hectares (250 acres) and 1000 mice in 1 hectare (2.5 acres). Often a population is too large to study in its entirety. Researchers examine such a population by sampling a part of it and then expressing the population in terms of density. Examples include the number of dandelions per square meter of lawn, the number of water fleas per liter of pond water, and the number of cabbage aphids per square centimeter of cabbage leaf. **Population density**, then, is the number of individuals of a species per unit of area or volume at a given time.

Different environments vary in the population density of any species they can support. This density may also vary in a single habitat from season to season or year to year. For example, red grouse are ground-dwelling game birds whose populations are managed for hunting. Consider two red grouse populations in the treeless moors of northwestern Scotland, at locations only 2.5 km (1.5 mi) apart. At one location the population density remained stationary during a three-year period, but at the other site it almost doubled in the first two years and then declined to its initial density in the third year. The reason was likely a difference in habitat. Researchers had experimentally burned the area where the population density increased initially and then decreased. Young heather shoots (*Calluna vulgaris*) produced after the burn provided nutritious food for the red grouse. So, population density may be determined in large part by biotic or abiotic factors in the environment that are external to the individuals in the population.

The individuals in a population often exhibit characteristic patterns of **dispersion**, or spacing, relative to one another. Individuals may be spaced in a random, clumped, or uniform dispersion. **Random dispersion** occurs when individuals in a population are spaced throughout an area in a manner that is unrelated to the presence of others (**FIG. 53-1a**). Of the three major types of dispersion, random dispersion is least common and hardest to observe in nature, leading some ecologists to question its existence. Trees of the same species, for example, sometimes appear to be distributed randomly in a tropical rain forest. However, an international team of 13 ecologists studied six tropical forest plots that were 25 to 52 hectares (62 to 130 acres) in area and reported that most of the 1000 tree species observed were clumped and not randomly dispersed. (Ecologists determine both clumped and uniform dispersion by statistically testing for differences from an assumed random distribution.) Random dispersion may occur infrequently because important environmental factors affecting dispersion usually do not occur at random. Flour beetle larvae in a container of flour are randomly dispersed, but their environment (flour) is unusually homogeneous.

(a) **Random dispersion**, illustrated for comparison, rarely, if ever, occurs in nature.

(b) **Clumped dispersion** is evident in the schooling behavior of certain fish species. Shown are bluestripe snappers (*Lutjanus kasmira*), photographed in Hawaii. This introduced fish, which grows to 30 cm (12 in.), may be displacing native fish species in Hawaiian waters.

(c) **Uniform dispersion** is characteristic of these nesting Cape gannets (*Morus capensis*) on the coast of South Africa. The birds space their nests more or less evenly.

Figure 53-1 Dispersion of individuals within a population

Perhaps the most common spacing is **clumped dispersion**, also called **aggregated distribution** or **patchiness**, which occurs when individuals are concentrated in specific parts of the habitat. Clumped dispersion often results from the patchy distribution of resources in the environment. It also occurs among animals because of the presence of family groups and

pairs, and among plants because of limited seed dispersal or asexual reproduction. An entire grove of aspen trees, for example, may originate asexually from a single plant. Clumped dispersion may sometimes be advantageous because social animals derive many benefits from their association. Many fish species, for example, associate in dense schools for at least part of their life cycle, possibly because schooling may reduce the risk of predation for any particular individual (**FIG. 53-1b**). The many pairs of eyes of schooling fish tend to detect predators more effectively than a single pair of eyes of a single fish. When threatened, schooling fish clump together more closely, making it difficult for a predator to single out an individual.

Uniform dispersion occurs when individuals are more evenly spaced than would be expected from a random occupation of a given habitat. A nesting colony of seabirds, in which the birds are nesting in a relatively homogeneous environment and place their nests at a more or less equal distance from one another, is an example of uniform dispersion (**FIG. 53-1c**). What might this spacing pattern tell us? In this case, uniform dispersion may occur as a result of nesting territoriality. Aggressive interactions among the nesting birds as they peck at one another from their nests cause each pair to place its nest just beyond the reach of nearby nesting birds. Uniform dispersion also occurs when competition among individuals is severe, when plant roots or leaves that have been shed produce toxic substances that inhibit the growth of nearby plants, or when animals establish feeding or mating territories.

Some populations have different spacing patterns at different ages. Competition for sunlight among same-aged sand pine in a Florida scrub community resulted in a change over time from either random or clumped dispersion when the plants were young to uniform dispersion when the plants were old. Sand pine is a fire-adapted plant with cones that do not release their seeds until they have been exposed to high temperatures (45°C to 50°C or higher). As a result of seed dispersal and soil conditions following a fire, the seedlings grow back in dense stands that exhibit random or slightly clumped dispersion. Over time, however, many of the more crowded trees tend to die from shading or competition, resulting in uniform dispersion of the surviving trees (**TABLE 53-1**).

CHECKPOINT 53.1

- What is the difference between population density and dispersion?
- **CONNECT** What are some biological advantages of a clumped dispersion? What are some disadvantages?

Table 53-1 Dispersion in a Sand Pine Population in Florida

Tree Trunks Examined	Density (per m ²)	Dispersion
All (alive and dead)	0.16	Random
Alive only	0.08	Uniform

53.2 Changes in Population Size

LEARNING OBJECTIVES

- 2 Explain the four factors (natality, mortality, immigration, and emigration) that produce changes in population size and solve simple problems involving these changes.
- 3 Define *intrinsic rate of increase* and *carrying capacity*, and explain the differences between J-shaped and S-shaped growth curves.

One goal of science is to discover common patterns among separate observations. As mentioned previously, population ecologists wish to understand general processes that are shared by many different populations, so they develop mathematical models based on equations that describe the dynamics of a single population. Population models are not perfect representations of a population, but models help illuminate complex processes. Moreover, mathematical modeling enhances the scientific process by providing a framework with which experimental population studies can be compared. We can test a model and see how it fits or does not fit with existing data. Data that are inconsistent with the model are particularly useful because they demand that we ask how the natural system differs from the mathematical model that we developed to explain it. As more knowledge accumulates from observations and experiments, the model is refined and made more precise.

Population size, whether of sunflowers, elephants, or humans, changes over time. On a global scale, this change is ultimately caused by two factors, expressed on a per capita (i.e., per individual) basis: **natality**, the average per capita birth rate; and **mortality**, the average per capita death rate. In humans the birth rate is usually expressed as the number of births per 1000 people per year and the death rate as the number of deaths per 1000 people per year.

To determine the rate of change in population size, we must also take into account the time interval involved, that is, the change in time. To express change in equations, we employ the Greek letter delta (Δ). In equation (1), ΔN is the change in the number of individuals in the population, Δt the change in time, N the number of individuals in the existing population, b the natality, and d the mortality.

$$(1) \Delta N / \Delta t = N(b - d)$$

The **growth rate** (r), or rate of change (increase or decrease) of a population on a per capita basis, is the birth rate minus the death rate:

$$(2) r = b - d$$

As an example, consider a hypothetical human population of 10,000 in which there are 200 births per year (i.e., by convention, 20 births per 1000 people) and 100 deaths per year (10 deaths per 1000 people):

$$r = 20/1000 - 10/1000 = 0.02 - 0.01 = 0.01, \text{ or } 1\% \text{ per year}$$

A modification of equation (1) tells us the rate at which the population is growing at a particular instant in time, that is, its instantaneous growth rate (dN/dt). (The symbols dN and dt are the mathematical differentials of N and t , respectively; they are not products, nor should the d in dN or dt be confused with the death rate, d .) Using differential calculus, this growth rate can be expressed as follows:

$$(3) dN/dt = rN$$

where N is the number of individuals in the existing population, t the time, and r the per capita growth rate.

Because $r = b - d$, if individuals in the population are born faster than they die, r is a positive value and population size increases. If individuals in the population die faster than they are born, r is a negative value and population size decreases. If r is equal to zero, births and deaths match, and population size is stationary despite continued reproduction and death.

Dispersal affects the growth rate in some populations

In addition to birth and death rates, **dispersal**, which is movement of individuals among populations, must be considered when examining changes in populations on a *local* scale. There are two types of dispersal: immigration and emigration. **Immigration** occurs when individuals enter a population and thus increase its size. **Emigration** occurs when individuals leave a population and thus decrease its size. The growth rate of a local population must take into account birth rate (b), death rate (d), immigration rate (i), and emigration rate (e) on a per capita basis. The per capita growth rate equals the birth rate minus the death rate, plus the immigration rate minus the emigration rate:

$$(4) r = (b - d) + (i - e)$$

For example, the growth rate of a human population of 10,000 that has 200 births (by convention, 20 per 1000), 100 deaths (10 per 1000), 10 immigrants (1 per 1000), and 100 emigrants (10 per 1000) in a given year would be calculated as follows:

$$r = (20/1000 - 10/1000) + (1/1000 - 10/1000) = 0.001, \text{ or } 0.1\% \text{ per year}$$

Each population has a characteristic intrinsic rate of increase

The maximum rate at which a population of a given species could increase under ideal conditions, when resources are abundant and its population density is low, is known as its **intrinsic rate of increase** ($r_{\max}$). Different species have different intrinsic rates of increase. A particular species' intrinsic rate of increase is influenced by several factors. They include the age at which reproduction begins, the fraction of the **lifespan** (duration of the individual's life) during which the individual

is capable of reproducing, the number of reproductive periods per lifetime, and the number of offspring the individual is capable of producing during each period of reproduction. These factors, which we discuss in greater detail later in the chapter, determine whether a particular species has a large or small intrinsic rate of increase.

Generally, large species such as blue whales and elephants have the smallest intrinsic rates of increase, whereas microorganisms have the greatest intrinsic rates of increase. Under ideal conditions (an environment with unlimited resources), certain bacteria can reproduce by binary fission every 20 minutes. At this rate of growth, a single bacterium would increase to a population of more than one billion in just ten hours!

If we plot the population size versus time under optimal conditions, the graph has a J shape that is characteristic of **exponential population growth**, which is the accelerating population growth rate that occurs when optimal conditions allow a constant per capita growth rate (FIG. 53-2). When a population grows exponentially, it grows faster as it gets larger.

Regardless of which species we are considering, whenever a population is growing at its intrinsic rate of increase, population size plotted versus time gives a curve of the same shape. The only variable is time. It may take longer for an elephant population than for a bacterial population to reach a certain size (because elephants do not reproduce as rapidly as bacteria), but both populations will always increase exponentially as long as their per capita growth rates remain constant.

No population can increase exponentially indefinitely

Certain populations may grow exponentially for brief periods. Exponential growth has been experimentally demonstrated in certain insects and in cultures of bacteria or protists (by continually supplying nutrients and removing waste products). However, organisms cannot reproduce indefinitely at their intrinsic rate of increase because the environment sets limits.

Figure 53-2 Exponential population growth

When bacteria divide every 20 minutes, their numbers (expressed in millions) increase exponentially. The curve of exponential population growth has a characteristic J shape. The ideal conditions under which bacteria or other organisms reproduce exponentially rarely occur in nature, and when they do, they are of short duration.

These limits include such unfavorable environmental conditions as the limited availability of food, water, shelter, and other essential resources (resulting in increased competition) as well as limits imposed by disease and predation.

In the earlier example, bacteria in nature would never be able to reproduce unchecked for an indefinite period because they would run out of food and living space, and poisonous wastes would accumulate in their vicinity. With crowding, bacteria would also become more susceptible to parasites (high population densities facilitate the spread of infectious organisms such as viruses among individuals) and predators (high population densities increase the likelihood of a predator catching an individual). As the environment deteriorated, their birth rate (b) would decline and their death rate (d) would increase. Conditions might worsen to a point where d would exceed b , and the population would decrease. The number of individuals in a population, then, is controlled by the ability of the environment to support it. As the number of individuals in a population (N) increases, environmental limits act to control population growth.

Over longer periods, the rate of population growth may decrease to nearly zero. This leveling out occurs at or near the limits of the environment to support the population. The **carrying capacity (K)** represents the largest population that can be maintained for an indefinite period by a particular environment, assuming that there are no changes in that environment. In nature the carrying capacity is dynamic and changes in response to environmental changes. An extended drought, for example, could decrease the amount of vegetation growing in an area; this change, in turn, would lower the carrying capacity for deer and other herbivores in that environment.

When a population regulated by environmental limits is plotted over longer periods, the curve has a characteristic S shape (FIG. 53-3). The curve shows the population's initial exponential increase (note the curve's J shape at the start, when environmental limits are few), followed by a leveling out as the carrying capacity of the environment is approached. The S-shaped growth curve, also called **logistic population growth**, can be modeled by a modified growth equation called a *logistic equation*. The logistic model of population growth was developed to explain population growth in continually breeding populations. Similar models exist for populations that have specific breeding seasons.

The logistic model describes a population increasing from a small number of individuals to a larger number of individuals that are ultimately limited by the environment. The logistic equation takes into account the carrying capacity of the environment:

$$(5) \frac{dN}{dt} = rN \left[\frac{K - N}{K} \right]$$

Note that part of the equation is the same as equation (3). The added element, $\left[\frac{K - N}{K} \right]$, reflects a decline in growth as a population size approaches its carrying capacity. When the number of organisms (N) is small, the rate of population growth is unchecked by the environment because the expression $\left[\frac{K - N}{K} \right]$ has a value of almost 1. As the population

Figure 53-3 Carrying capacity and logistic population growth

In many laboratory studies, exponential population growth slows as the carrying capacity (K) of the environment is approached. The logistic model of population growth, when plotted, has a characteristic S-shaped curve.

(N) begins to approach the carrying capacity (K), however, the growth rate declines because the value of $\left[\frac{K - N}{K} \right]$ approaches zero.

Although the S curve is an oversimplification of how most populations change over time, it does appear to fit some populations that have been studied in the laboratory as well as a few that have been studied in nature. For example, Georgyi F. Gause, a Russian ecologist who conducted experiments during the 1930s, grew a population of a single species, *Paramecium caudatum*, in a test tube. He supplied a limited amount of food (bacteria) daily and replenished the growth medium occasionally to eliminate the accumulation of metabolic wastes. Under these conditions, the population of *P. caudatum* increased exponentially at first; then its growth rate declined to zero, and the population size leveled off (see Fig. 54-5, middle graph).

A population rarely stabilizes at K (carrying capacity), but it may temporarily rise higher than K . It will then drop back to, or below, the carrying capacity. Sometimes a population that overshoots K will experience a *population crash*, an abrupt decline from high to low population density. Such an abrupt change is commonly observed in bacterial cultures, zooplankton, and other populations whose resources have been exhausted.

The carrying capacity for reindeer, which live in cold northern habitats, is determined largely by the availability of winter forage. In 1910, humans introduced a small herd of 26 reindeer onto one of the Pribilof Islands of Alaska. The herd's population increased exponentially for about 25 years until there were approximately 2000 reindeer, many more than the island could support, particularly in winter. The reindeer overgrazed the vegetation until the plant life was almost wiped out. Then, in slightly longer than a decade, as reindeer died from starvation, the number of reindeer plunged to 8, one-third the size of the original introduced population. Recovery of subarctic and arctic vegetation after overgrazing by reindeer can take 15 to 20 years, during which time the carrying capacity for reindeer is greatly reduced.

CHECKPOINT 53.2

- What effect does each of the following have on population size: natality, mortality, immigration, and emigration?
- **CONNECT** How does a J-shaped population growth curve differ from an S-shaped curve in terms of intrinsic rate of increase and carrying capacity?
- **VISUALIZE** Sketch simple graphs representing the long-term growth of two populations of bacteria cultured in test tubes, one in which the nutrient medium is replenished and the other in which it is not replenished.

53.3 Factors Influencing Population Size

LEARNING OBJECTIVE

- 4 Contrast the influences of density-dependent and density-independent factors on population size and give examples of each.

Certain natural mechanisms influence population size. Factors that affect population size fall into two categories: density-dependent factors and density-independent factors. These two sets of factors vary in importance from one species to another and, in most cases, probably interact simultaneously to determine the size of a population.

Density-dependent factors regulate population size

Sometimes the influence of an environmental factor on the individuals in a population varies with the density or crowding of that population. If a change in population density alters how an environmental factor affects that population, the environmental factor is said to be a **density-dependent factor**.

As population density increases, density-dependent factors tend to slow population growth by causing an increase in death rate and/or a decrease in birth rate. The effect of these density-dependent factors on population growth increases as the population density increases; that is, density-dependent factors affect a larger proportion, not just a larger number, of the population. Density-dependent factors can also affect population growth when population density declines by decreasing the death rate and/or increasing the birth rate. Thus, density-dependent factors tend to regulate a population at a relatively constant size that is near the carrying capacity of the environment. (Keep in mind, however, that the carrying capacity of the environment frequently changes.) Density-dependent factors are an excellent example of a **negative feedback system** (FIG. 53-4).

Predation, disease, and competition are examples of density-dependent factors. As the density of a population increases, predators are more likely to find an individual of a given prey species than before. When population density

Figure 53-4 Density-dependent factors and negative feedback

When the number of individuals in a population increases, density-dependent factors cause a decline in the population. When the number of individuals in a population decreases, a relaxation of density-dependent factors allows the population to increase.

is high, the members of a population encounter one another more frequently than previously, and the chance of their transmitting parasites and infectious disease organisms increases. As population density increases, so does competition for resources such as living space, food, cover, water, minerals, and sunlight; eventually, the point may be reached at which many members of a population fail to obtain the minimum amount of whatever resource is in shortest supply. At higher population densities, density-dependent factors raise the death rate and/or lower the birth rate, inhibiting further population growth. The opposite effect occurs when the density of a population decreases. Predators are less likely to encounter individual prey, parasites and infectious diseases are less likely to be transmitted from one host to another, and competition among members of the population for resources such as living space and food declines.

Density-dependent factors may explain what makes certain populations fluctuate cyclically over time

Lemmings are small, stumpy-tailed rodents that are found in colder regions of the Northern Hemisphere (FIG. 53-5). They are herbivores that feed on sedges and grasses in the Arctic tundra. It has long been known that lemming populations have a three- to four-year cyclical oscillation that is often described as “boom or bust.” That is, the population increases dramatically and then crashes; the population peaks may be 100 times as high as the low points in the population cycle. Many other populations, such as snowshoe hares and red grouse, also exhibit cyclic fluctuations.

What is the driving force behind these fluctuations? Several hypotheses have been proposed to explain the cyclical periodicity of lemming and other boom-or-bust populations, and many involve density-dependent factors. One possibility is that as a prey population becomes more dense, it overwhelms its food supply; as a result, the population declines. In the lemming example, researchers have studied the shape of several lemming population curves during their oscillations; the data suggest that lemming populations crash because they overgraze the plants, not because predators eat them.

Another explanation is that the population density of predators, such as long-tailed jaegers (birds related to gulls that eat lemmings), increases in response to the increasing density of prey. Few jaegers breed when the lemming population is low. However, when the lemming population is high, most jaegers breed, and the number of eggs per clutch is greater than usual. As more predators consume the abundant prey, the prey population declines. Later, with fewer prey in an area, the population of predators declines (some disperse out of the area, and fewer offspring are produced).

In a long-term study of collared lemmings in Greenland, researchers at the University of Helsinki, Finland, observed four-year cycles of lemming population density that were not affected by availability of food or living space. They developed a model in which the fluctuations in the lemming population are most accurately predicted by those of another species, the stoat. The population of the stoat, a member of the weasel family that preys almost exclusively on lemmings, peaks a year after a peak in the lemming population. On the other hand, populations of three other lemming predators—snowy owls, arctic foxes, and long-tailed skuas (birds related to gulls)—respond more immediately to changes in the lemming population and thus tend to stabilize the population cycle established by the stoats.

Figure 53-5 Lemming

The brown lemming (*Lemmus trimucronatus*) lives in the Arctic tundra. Although lemming populations have been studied for decades, much about the cyclic nature of lemming population oscillations and their effects on the rest of the tundra ecosystem is still not well understood. This species ranges from Alaska eastward to the Hudson Bay.

Climate change may also be affecting lemming population dynamics. Researchers from the University of Oslo, Norway, and a group of international collaborators have observed a correlation between climate and lemming cycles. They found that lemming populations increase in the years in which they can survive by eating moss in the space between the ground and the snow pack. Populations are reduced in warmer years, when slight melting and refreezing of the snow eliminates this space.

Parasites may also interact with their hosts to cause regular cyclic fluctuations. Detailed studies of red grouse have shown that even managed populations in wildlife preserves may have significant cyclic oscillations. Reproduction in red grouse is related to the density of parasitic nematodes (roundworms) living in adult intestines. Fewer birds breed successfully when adults are infected with worms; thus, a high density of worms leads to a population crash. Hypothesizing that red grouse populations fluctuate in response to the parasites, ecologists at the University of Stirling in Scotland successfully reduced or eliminated population fluctuations in several red grouse populations. They did so by catching and orally treating the birds with a chemical that causes worms to be ejected from their bodies.

Competition is an important density-dependent factor Competition is an interaction among two or more individuals that attempt to use the same essential resource, such as food, water, sunlight, or living space, that is in limited supply. The use of the resource by one of the individuals reduces the availability of that resource for other individuals. Competition occurs both within a given population (**intraspecific competition**) and among populations of different species (**interspecific competition**). We consider the effects of intraspecific competition here; interspecific competition is discussed in Chapter 54.

Individuals of the same species compete for a resource in limited supply by interference competition or by exploitation competition. In **interference competition**, also called **contest competition**, certain dominant individuals obtain an adequate supply of the limited resource at the expense of other individuals in the population; that is, the dominant individuals actively interfere with other individuals' access to resources. In **exploitation competition**, also called **scramble competition**, all the individuals in a population "share" the limited resource more or less equally so that at high population densities none of them obtains an adequate amount. The populations of species in which exploitation competition operates often oscillate over time, and there is always a risk that the population size will drop to zero. In contrast, those species in which interference competition operates experience a relatively small drop in population size, caused by the death of individuals that are unable to compete successfully.

Intraspecific competition among red grouse involves interference competition. When red grouse populations are small, the birds are less aggressive, and most young birds establish a feeding territory (an area defended against other members of the same species). However, when the population is large, establishing a territory is difficult because there are more birds than there are territories and the birds are therefore

much more aggressive. Those birds without territories often die from predation or starvation. Thus, birds with territories use a larger share of the limited resource (the territory with its associated food and cover), whereas birds without territories cannot compete successfully.

The moose population on Isle Royale, Michigan, the largest island in Lake Superior, provides a vivid example of exploitation competition that is similar to that of the reindeer population on the Pribilof Islands (discussed earlier). Isle Royale differs from most islands in that large mammals can walk to it when the lake freezes over in winter. The minimum distance to be walked is 24 km (15 mi), however, so this movement has happened infrequently. Around 1900, a small herd of moose wandered across the ice of frozen Lake Superior and reached the island for the first time. By 1934, the moose population on the island had increased to about 3000 and had consumed almost all the edible vegetation. In the absence of this food resource, there was massive starvation in 1934. More than 60 years later, in 1996, a similar die-off claimed more than 60% of the moose after they had again increased to a high density. Thus, exploitation competition for scarce resources can result in dramatic population oscillations.

The effects of density-dependent factors are difficult to assess in nature Most studies of density dependence have been conducted in laboratory settings where all density-dependent (and density-independent) factors except one are controlled experimentally. Populations in natural settings, however, are exposed to a complex set of variables that continually change. As a result, in natural communities it is difficult to evaluate the relative effects of different density-dependent factors.

Ecologists from the University of California, Davis, noted that few spiders occur on tropical islands inhabited by lizards, whereas more spiders and more species of spiders are found on lizard-free islands. Deciding to study these observations experimentally, David Spiller and Thomas Schoener staked out plots of vegetation (mainly seagrape shrubs) and enclosed some of them with lizard-proof screens (**FIG. 53-6**). Some of the plots were emptied of all lizards; each control enclosure had approximately nine lizards. Nine web-building spider species were observed in the enclosures. Spiders were counted approximately 30 times from 1989 to 1994. During the 4.5 years of observations reported here, spider population densities were higher in the lizard-free enclosures than in enclosures with lizards. Moreover, the enclosures without lizards had more species of spiders. Therefore, we might conclude that lizards control spider populations.

Even this relatively simple experiment, though, may be explained by a combination of two density-dependent factors: predation (lizards eat spiders) and interspecific competition (lizards compete with spiders for insect prey; i.e., both spiders and lizards eat insects). In this experiment the effects of the two density-dependent factors in determining spider population size cannot be evaluated separately. Additional lines of evidence support the actions of both competition and predation at these sites.

Key Experiment

What is the influence of density-dependent factors on population size in a natural habitat?

HYPOTHESIS: Lizards reduce the size of spider populations.

EXPERIMENT: Researchers conducted a field experiment in which they constructed enclosed plots; spiders and insects could pass freely into and out of the enclosures, but the lizards could not. There were several lizard species in the study, but over 90% of the individuals were brown anoles, *Anolis sagrei* (see photograph). Some plots included lizards; the other plots were lizard-free. The spiders were periodically counted over a period of 4.5 years. An earlier experiment indicated that the enclosures themselves have no effect on the number of web-building spiders.

NNeiring/istockphoto.com

RESULTS AND CONCLUSION: The graph of the mean number of web-building spiders at each count per enclosure with lizards (*control*, blue) and per enclosure with lizards removed (*red*) demonstrates that the number of web-building spiders was consistently higher in the absence of lizards. Lizards may control spider populations by preying on them, by competing with them for insect prey, or by a combination of these factors.

Figure 53-6 Interaction of density-dependent factors

PREDICT Note that the spider populations fluctuated during the experiment, although the lizard-free populations were consistently larger. Formulate a hypothesis relating to whether such fluctuations are due to biotic factors, abiotic factors, or a combination, and devise a way to test it.

Density-independent factors are generally abiotic

Any environmental factor that affects the size of a population but is not influenced by changes in population density is called a **density-independent factor**. Such factors are typically abiotic. Random weather events that reduce population size serve as density-independent factors. They often affect population density in unpredictable ways. A killing frost, severe blizzard, or hurricane, for example, may cause extreme and irregular reductions in a vulnerable population, regardless of its size, and thus may be considered largely density-independent.

Consider a density-independent factor that influences mosquito populations in arctic environments. These insects produce several generations per summer and achieve high population densities by the end of the season. A shortage of food does not seem to be a limiting factor for mosquitoes, nor is there any shortage of ponds in which to breed. What puts a stop to the skyrocketing mosquito population is winter. Not a single adult mosquito survives winter, and the entire population must grow afresh the next summer from the few eggs and hibernating larvae that survive. Thus, severe winter weather is a density-independent factor that affects arctic mosquito populations.

Density-independent and density-dependent factors are often inter-related. Social animals, for example, often resist dangerous weather conditions by collective behavior, as in the case of sheep huddling together in a snowstorm. In this case it appears that the greater the population density of the sheep, the better their ability to resist the environmental stress of a density-independent event (such as a snowstorm).

CHECKPOINT 53.3

- What are three examples of density-dependent factors that affect population growth?
- What are three density-independent factors?

53.4 Life History Traits

LEARNING OBJECTIVES

- 5 Contrast semelparous and iteroparous reproduction.
- 6 Distinguish among species exhibiting an r strategy, those with a K strategy, and those that do not easily fit either category.
- 7 Describe Type I, Type II, and Type III survivorship curves and explain how life tables and survivorship curves indicate mortality and survival.

Each species is uniquely suited to its lifestyle. Many years pass before a young magnolia tree flowers and produces seeds, whereas an annual plant grows from seed, flowers, and dies within a single season. A mating pair of black-browed albatrosses produces a single chick every year, but a mating pair of gray-headed albatrosses produces a single chick biennially (every other year).

Species that expend their energy in a single, immense reproductive effort are said to be **semelparous**. Most insects and invertebrates, many plants, and some species of fish exhibit semelparity. Pacific salmon, for example, hatch in fresh water and swim to the ocean, where they live until they mature. Adult salmon swim from the ocean back into the same rivers or streams in which they hatched to spawn (reproduce). After they spawn, the salmon die.

Agaves are semelparous plants that are common in arid tropical and semitropical areas. The thick, fleshy leaves of the agave plant are crowded into a rosette at the base of the stem. Commonly called the century plant because it was mistakenly thought to flower only once in a century, agaves can flower after they are ten years old or so, after which the entire plant dies (FIG. 53-7).

Many species are **iteroparous** and exhibit repeated reproductive cycles—that is, reproduction during several breeding seasons—throughout their lifetimes. Iteroparity is common in most vertebrates as well as in perennial herbaceous plants, shrubs, and trees. The timing of reproduction, earlier or later in life, is a crucial aspect of iteroparity and involves trade-offs. On the one hand, reproducing earlier in life may mean a reduced likelihood of survival (because an individual is expending energy toward reproduction instead of its own

R. Gustafson/Visuals Unlimited

Figure 53-7 Semelparity

Agaves flower once and then die. The agave is a succulent with sword-shaped leaves arranged as a rosette around a short stem. Shown is *Agave shawii*, whose leaves grow to 61 cm (2 ft). Note the floral stalk, which can grow more than 3 m (10 ft) tall.

growth), which reduces the potential for later reproduction. On the other hand, reproducing later in life means that the individual has less time for additional reproductive events.

Ecologists try to understand the adaptive consequences of various **life history traits**, such as semelparity and iteroparity. Adaptations such as reproductive rate, age at maturity, and **fecundity** (potential capacity to produce offspring), all of which are a part of a species' life history traits, influence an organism's survival and reproduction. The ability of an individual to reproduce successfully, thereby making a genetic contribution to future generations of a population, is called its **fitness** (recall the discussion of fitness in Chapter 19).

Although many different life histories exist, some ecologists recognize two extremes: r -selected species and K -selected species. As you read the following descriptions of r selection and K selection, keep in mind that these concepts, although useful, oversimplify most life histories. Species tend to possess a combination of r -selected and K -selected traits as well as traits that cannot be classified as either r -selected or K -selected. In addition, some populations within a species may exhibit the characteristics of r selection, whereas other populations in different environments may assume K -selected traits.

Populations described by the concept of ***r* selection** have traits that contribute to a high population growth rate. Recall that *r* designates the per capita growth rate. Because such organisms have a high *r*, biologists call them ***r* strategists** or ***r*-selected species**. Small body size, early maturity, short life-span, large broods, and little or no parental care are typical of many *r* strategists, which are usually opportunists found in variable, temporary, or unpredictable environments where the probability of long-term survival is low. Some of the best representatives of *r* strategists are insects and many annual plants. For example, following a rainy period, desert annuals rapidly grow from seed, flower and set seed, and then die.

In populations described by the concept of ***K* selection**, traits maximize the chance of surviving in an environment where the number of individuals is near the carrying capacity (*K*) of the environment. These organisms, called ***K* strategists** or ***K*-selected species**, do not produce large numbers of offspring. They characteristically have long lifespans with slow development, late reproduction, large body size, and a low reproductive rate. *K* strategists tend to be found in relatively constant or stable environments, where they have a high competitive ability. Redwood trees as well as most tropical rain-forest trees are classified as *K* strategists. Animals that are *K* strategists typically invest in parental care of their young. Tawny owls (*Strix aluco*), for example, are *K* strategists that pair-bond for life, with both members of a pair living and hunting in adjacent, well-defined territories. Their reproduction is regulated in accordance with the resources, especially the food supply, present in their territories. In an average year, 30% of the birds do not breed at all. If food supplies are more limited than initially indicated, many of those that do breed fail to incubate their eggs. Rarely do the owls lay the maximum number of eggs that they are physiologically capable of laying, and breeding is often delayed until late in the season, when the rodent populations on which they depend have become large. Thus, the behavior of tawny owls ensures better reproductive success of the individual and leads to a stable population at or near the carrying capacity of the environment. Starvation, an indication that the tawny owl population has exceeded the carrying capacity, rarely occurs.

Life tables and survivorship curves indicate mortality and survival

A **life table** can be constructed to show the mortality and survival data of a population or **cohort**, a group of individuals of the same age, at different times during their lifespan. Insurance companies were the first to use life tables, using them to calculate the relationship between a client's age and the likelihood of the client surviving to pay enough insurance premiums to cover the cost of the policy. Ecologists construct such tables for animals and plants based on data that rely on a variety of population sampling methods and age determination techniques.

TABLE 53-2 shows a life table for a cohort of 530 gray squirrels. The first two columns show the units of age (years) and the number of individuals in the cohort that were alive at the beginning of each age interval (the actual data collected in the field by the ecologist). The values for the third column (the proportion alive at the beginning of each age interval) are calculated by dividing each number in column 2 by 530, the number of squirrels in the original cohort. The values in the fourth column (the proportion dying during each age interval) are calculated using the values in the third column and subtracting the number of survivors at the beginning of the next interval from those alive at the beginning of the current interval. For example, the proportion dying during interval 0–1 years is $1.000 - 0.253 = 0.747$. The far right column, the death rate for each age interval, is calculated by dividing the proportion dying during the age interval (column 4) by the proportion alive at the beginning of the age interval (column 3). For example, the death rate for the age interval 1–2 years is $0.147 \div 0.253 = 0.581$.

Survivorship is the probability that a given individual in a population or cohort will survive to a particular age. Plotting the logarithm (base 10) of the number of surviving individuals against age, from birth to the maximum age reached by any individual, produces a **survivorship curve**. **FIGURE 53-8** shows the three main survivorship curves that ecologists recognize.

In *Type I survivorship*, as exemplified by bison and humans, the young and those at reproductive age have a high probability of surviving. The probability of survival decreases more rapidly with increasing age; mortality is concentrated later in

Table 53-2 Life Table for a Cohort of 530 Gray Squirrels (*Sciurus carolinensis*)

Age Interval (years)	Number Alive at Beginning of Age Interval	Proportion Alive at Beginning of Age Interval	Proportion Dying during Age Interval	Death Rate for Age Interval
0–1	530	1.000	0.747	0.747
1–2	134	0.253	0.147	0.581
2–3	56	0.106	0.032	0.302
3–4	39	0.074	0.031	0.418
4–5	23	0.043	0.021	0.488
5–6	12	0.022	0.013	0.591
6–7	5	0.009	0.006	0.666
7–8	2	0.003	0.003	1.000
8–9	0	0.000	0.000	—

Figure 53-8 Survivorship curves

These curves represent the ideal survivorships of species in which mortality is greatest in old age (Type I), spread evenly across all age groups (Type II), and greatest among the young (Type III). The survivorship of most organisms can be compared to these curves.

life. **FIGURE 53-9** shows a survivorship curve for a natural population of Drummond phlox, an annual native to East Texas that became widely distributed in the southeastern United States after it escaped from cultivation. Because most Drummond phlox seedlings survive to reproduce, after germination the plant exhibits a Type I survivorship that is typical of annuals.

Figure 53-9 Survivorship curve for a Drummond phlox population

Drummond phlox has a Type I survivorship after germination of the seeds. Bars above the graph indicate the various stages in the Drummond phlox life history. Data were collected from Nixon, Texas, in 1974 and 1975. Survivorship on the y-axis begins at 0.296 instead of 1.00 because the study took into account death during the seed dormancy period prior to germination (*not shown*). Adapted from Leverich, W.J., and D.A. Levin, "Age-Specific Survivorship and Reproduction in *Phlox drummondii*," *American Naturalist*, Vol. 113, No. 6 (1979): 1148. Copyright © 1979 University of Chicago Press. Reprinted with permission.

In *Type III survivorship*, the probability of mortality is greatest early in life, and those individuals that avoid early death subsequently have a high probability of survival, that is, the probability of survival increases with increasing age. Type III survivorship is characteristic of oysters; young oysters have three free-swimming larval stages before settling down and secreting a shell. These larvae are vulnerable to predation, and few survive to adulthood.

In *Type II survivorship*, which is intermediate between Types I and III, the probability of survival does not change with age. The probability of death is equally likely across all age groups, resulting in a linear decline in survivorship. This constancy probably results from essentially random events that cause death with little age bias. Although this relationship between age and survivorship is rare, some lizards have Type II survivorship.

The three survivorship curves are generalizations, and few populations exactly fit one of the three. Some species have one type of survivorship curve early in life and another type as adults. Herring gulls, for example, start out with a Type III survivorship curve but develop a Type II curve as adults (**FIG. 53-10**). The survivorship curve shown in this figure is characteristic of birds in general. Note that most death occurs almost immediately after hatching, despite the protection and care given to the chicks by the parent bird. Herring gull chicks die from predation or attack by other herring gulls, inclement weather, infectious diseases, or starvation following death of the parent. Once the chicks become independent, their survivorship increases dramatically, and death occurs at about the same rate throughout their remaining lives. Few or no herring gulls die from the degenerative diseases of "old age" that cause death in most humans.

Figure 53-10 Survivorship curve for a herring gull population

Herring gulls (*Larus argentatus*) have Type III survivorship as chicks and Type II survivorship as adults. Data were collected from Kent Island, Maine, during a five-year period in the 1930s; baby gulls were banded to establish identity. The very slight increase just prior to 20 years of age is due to sampling error. Adapted from Paynter, R.A., Jr., "A New Attempt to Construct Lifetables for Kent Island Herring Gulls," *Bulletin of the Museum of Comparative Zoology*, Vol. 133, No. 11 (1966): 489–528.

CHECKPOINT 53.4

- What are the advantages of semelparity? of iteroparity? Are there disadvantages?
- **CONNECT** Why is parental care of young a common characteristic of *K* strategists?
- Do all survivorship curves neatly fit the Type I, II, or III models? Explain.

53.5 Metapopulations

LEARNING OBJECTIVE

- 8** Define *metapopulation* and distinguish between source habitats and sink habitats.

The natural environment is a heterogeneous **landscape** consisting of interacting ecosystems that provide a variety of habitat patches. Landscapes, which are typically several to many square kilometers in area, cover larger land areas than individual ecosystems. Consider a forest, for example. The forest landscape is a mosaic of different elevations, temperatures, levels of precipitation, soil moisture, soil types, and other properties. Because each species has its own habitat requirements, this heterogeneity in physical properties is reflected in

Jerry Whaley/Getty Images

(a) This early spring view from Newfound Gap Rd., Great Smoky Mountains National Park, gives some idea of the heterogeneity of the landscape. During the summer, when all the vegetation is a deep green, the landscape appears homogeneous.

the different organisms that occupy the various patches in the landscape (FIG. 53-11). Some species occur in very narrow habitat ranges, whereas others have wider habitat distributions.

Population ecologists have discovered that many species are not distributed as one large population across the landscape. Instead, many species exist as a series of local populations distributed in distinct habitat patches. Each local population has its own characteristic demographic features, such as birth, death, emigration, and immigration rates. A population that is divided into several local populations among which individuals occasionally disperse (emigrate and immigrate) is known as a **metapopulation**. For example, note the various local populations of red oak on the mountain slope in Figure 53-11b.

The spatial distribution of a species occurs because different habitats vary in suitability, from unacceptable to preferred. The preferred sites are more productive habitats that increase the likelihood of survival and reproductive success for the individuals living there. Good habitats, called **source habitats**, are areas where local reproductive success is greater than local mortality. *Source populations* generally have greater population densities than populations at less suitable sites, and surplus individuals in the source habitat disperse and find another habitat in which to settle and reproduce.

Individuals living in lower quality habitats may suffer death or, if they survive, poor reproductive success. Lower quality habitats, called **sink habitats**, are areas where local reproductive success is less than local mortality. Without immigration from other areas, a *sink population* declines until

(b) An evaluation of the distribution of vegetation on a typical west-facing slope in the Great Smoky Mountains National Park reveals that the landscape consists of patches. Chestnut oak is a species of oak (*Quercus prinus*); chestnut heath is an area within chestnut oak forest where the trees are widely scattered and the slopes underneath are covered by a thick growth of laurel (*Kalmia*) shrubs; cove forest is a mixed stand of deciduous trees.

Figure 53-11 The mosaic nature of landscapes

KEY

- Source population in a suitable habitat
- Sink population in a low-quality habitat
- Individual within a local population
- Dispersal event

Figure 53-12 Source and sink populations in a hypothetical metapopulation

The local populations in the habitat patches shown here collectively make up the metapopulation. Source habitats provide individuals that emigrate and colonize sink habitats. Studied over time, the metapopulation is shown to exist as a shifting pattern of occupied and vacant habitat patches.

extinction occurs. If a local population becomes extinct, individuals from a source habitat may recolonize the vacant habitat at a later time. Source and sink habitats, then, are linked to one another by dispersal (FIG. 53-12).

Metapopulations are becoming more common as humans alter the landscape by fragmenting existing habitats to accommodate homes and factories, agricultural fields, and logging. As a result, the concept of metapopulations, particularly as it relates to endangered and threatened species, has become an important area of study in conservation biology.

CHECKPOINT 53.5

- **CONNECT** What roles do source habitats and sink habitats play in the dynamic nature of a metapopulation?

53.6 Human Populations

LEARNING OBJECTIVES

- 9 Summarize the history of human population growth.
- 10 Explain how highly developed and developing countries differ in population characteristics such as infant mortality rate, total fertility rate, replacement-level fertility, and age structure.
- 11 Distinguish between people overpopulation and consumption overpopulation.

Now that we have examined some of the basic concepts of population ecology, we can apply those concepts to the human population. Examine FIGURE 53-13, which shows the world

increase in the human population since the development of agriculture approximately 10,000 years ago. Now look back at Figure 53-2 and compare the two curves. The characteristic J curve of exponential population growth shown in Figure 53-13 reflects the decreasing amount of time it has taken to add each additional billion people to our numbers. It took thousands of years for the human population to reach 1 billion, a milestone that took place around 1800. It took 130 years to reach 2 billion (in 1930), 30 years to reach 3 billion (in 1960), 15 years to reach 4 billion (in 1975), 12 years to reach 5 billion (in 1987), and 12 years to reach 6 billion (in 1999). The world population reached 7.5 billion in 2017, and the United Nations projects that it will rise to more than 8.5 billion by 2030.

Thomas Malthus (1766–1834), a British clergyman and economist, was one of the first to recognize that the human population cannot continue to increase indefinitely (see Chapter 18). He pointed out that human population growth is not always desirable (a view contrary to the beliefs of his day and to those of many people even today) and that the human population is capable of increasing faster than the food supply. He maintained that the inevitable consequences of population growth are famine, disease, and war.

The world population is currently increasing by about 100 million people per year. This rise is not caused by an increase in the birth rate (b). In fact, the world birth rate has actually declined during the past 200 years. The increase in population is due instead to a dramatic decrease in the death rate (d). This decrease in mortality has occurred primarily because greater food production, better medical care, and improved sanitation practices have increased the life expectancies of a great majority of the global population. For example, from 1920 to 2000, the death rate in Mexico fell from approximately 40 per 1000 individuals to 4 per 1000, whereas the birth rate dropped from approximately 40 per 1000 individuals to 24 per 1000 (FIG. 53-14). As of 2017

Figure 53-13 Human population growth

During the last 1000 years, the human population has been increasing nearly exponentially. Population experts predict that the population will level out during the 21st century, forming the S curve observed in other species. (Black Death refers to a devastating disease, probably bubonic plague, that decimated Europe and Asia in the 14th century.)

Figure 53-14 Birth and death rates in Mexico, 1900 to 2000

Both birth and death rates declined during the 20th century, but because the death rate declined much more than the birth rate, Mexico has experienced a high growth rate. (The high death rate prior to 1920 was caused by the Mexican Revolution; Population Reference Bureau.)

Mexico's birth rate had continued to fall, to about 20 per 1000; its death rate increased slightly to 5 per 1000. (As a population's birth rate falls, its death rate tends to increase somewhat because of an increase in the average age of the population.)

The human population has reached a turning point. Although our numbers continue to increase, the world per capita growth rate (r) has declined over the past several years, from a peak of 2.2% per year in the mid-1960s to 1.2% per year in 2017. Population experts at the United Nations and the World Bank have projected that the growth rate may continue to slowly decrease until zero population growth is attained. Thus, exponential growth of the human population may end, and if it does, the S curve will replace the J curve. Demographers project that **zero population growth**, the point at which the birth rate equals the death rate ($r = 0$), will occur toward the end of the 21st century.

The latest (2017) projections available through the Population Reference Bureau, based on data from the United Nations, forecast that the human population will exceed 9.8 billion in the year 2050. This forecast is a "medium" projection; such population projections are "what-if" exercises. Given certain assumptions about future tendencies in natality, mortality, and dispersal, population experts can calculate an area's population for a given number of years into the future. Population projections indicate the changes that may occur, but they must be interpreted with care because they vary depending on what assumptions have been made. Small differences in fertility as well as death rates produce large differences in population forecasts.

The main unknown factor in any population growth scenario is Earth's carrying capacity. According to Joel Cohen of

the Earth Institute at Columbia University, most published estimates of how many people Earth can support range from 4 billion to 16 billion. These estimates vary so widely because of the assumptions that are made about standard of living, resource consumption, technological innovations, and waste generation. If we want all people to have a high level of material well-being equivalent to the lifestyles common in highly developed countries, Earth will clearly be able to support far fewer humans than if everyone lives just above the subsistence level. Thus, Earth's carrying capacity for the human population is not decided simply by natural environmental constraints. Human choices and values have to be factored into the assessment.

It is also not clear what will happen to the human population if or when the carrying capacity is approached. Optimists suggest that the human population will stabilize because of a decrease in the birth rate. Some experts take a more pessimistic view and predict that the widespread degradation of our environment caused by our ever-expanding numbers will make Earth uninhabitable for humans and other species. These experts contend that a massive wave of human suffering and death will occur. Some experts think that the human population has already exceeded the carrying capacity of the environment, a potentially dangerous situation that threatens our long-term survival as a species.

Not all countries have the same growth rate

Although world population figures illustrate overall trends, they do not describe other important aspects of the human population story, such as population differences from country to country. Human **demographics**, the science that deals with human population statistics such as size, density, and distribution, provides information on the populations of various countries. As you probably know, not all parts of the world have the same rates of population increase. Countries can be classified into two groups, highly developed and developing, based on their rates of population growth, degrees of industrialization, and relative prosperity (**TABLE 53-3**).

Highly developed countries, such as the United States, Canada, France, Germany, Sweden, Australia, and Japan, have low rates of

Table 53-3 Comparison of 2017 Population Data in Selected Developed and Developing Countries

	Developed (Highly Developed) United States	Developing (Moderately Developed) Brazil	(Less Developed) Ethiopia
Fertility rate	1.8	1.6	4.6
Doubling time	175 years	100 years	27 years
Infant mortality rate	5.8 per 1000	14 per 1000	48 per 1000
Life expectancy at birth	79 years	76 years	65 years
GNI PPP per capita (U.S. \$)	\$58,030	\$14,810	\$1,730
Married women 15–49 using modern contraception	70%	77%	35%

Data from Population Reference Bureau.

population growth and are highly industrialized relative to the rest of the world. Highly developed countries have the lowest birth rates in the world. Indeed, some highly developed countries such as Germany have birth rates just below that needed to sustain the population and are thus declining slightly in numbers. Highly developed countries also have low **infant mortality rates** (the number of infant deaths per 1000 live births). The infant mortality rate of the United States in 2017 was 5.8, compared with a world infant mortality rate of 32.

Highly developed countries also have longer life expectancies (79 years at birth in the United States versus 72 years worldwide) and higher average GNI PPP per capita (\$58,030 in the United States versus \$16,101 worldwide) than other countries. GNI PPP per capita is gross national income (GNI) in purchasing power parity (PPP) divided by midyear population. It indicates the amount of goods and services an average citizen of that particular region or country could buy in the United States.

Developing countries fall into two subcategories: moderately developed and less developed. Mexico, Turkey, Thailand, and most countries of South America are examples of *moderately developed countries*. Their birth rates and infant mortality rates are generally higher than those of highly developed countries, but the rates are declining. Moderately developed countries have a medium level of industrialization, and their average GNI PPP per capita is lower than those of highly developed countries.

Bangladesh, Niger, Ethiopia, Laos, and Cambodia are examples of *less developed countries*. These countries have the highest birth rates, the highest infant mortality rates, the lowest life expectancies, and the lowest average GNI PPP per capita in the world.

One way to represent the population growth of a country is to determine the **doubling time**, the amount of time it would take for its population to double in size assuming that its current growth rate did not change. A simplified formula for doubling time (t_d) is $t_d = 70 \div r$. (The actual formula involves calculus and is beyond the scope of this text. This simplified formula actually has many practical applications; e.g., you can use it to estimate how long it will take to double your money in a savings account at a specific rate of compound interest.)

A look at a country's doubling time identifies it as a highly, moderately, or less developed country: the shorter the doubling time, the less developed the country. At rates of growth in 2017, the approximate doubling time is 27 years for Ethiopia, 41 years for Laos, 58 years for Turkey, 175 years for the United States, and 233 years for France.

It is also instructive to examine **replacement-level fertility**, the number of children a couple must produce to “replace” themselves. Replacement-level fertility is usually given as 2.1 children in highly developed countries and 2.7 children in developing countries. The number is always greater than 2.0 because some children die before they reach reproductive age. Higher infant mortality rates are the main reason that replacement levels in developing countries are greater than in highly developed countries. The **total fertility rate**—the average number of children born to a woman during her lifetime—is 2.5 worldwide, which is well above replacement levels. However, it has fallen below replacement levels, to 1.7, in the highly developed countries. The total fertility rate in the United States is 1.8, which is higher than in other industrialized countries.

The population in many developing countries is beginning to approach stabilization. The fertility rate must decline for the population to stabilize (**TABLE 53-4**; note the general decline in total fertility rate from the 1960s to 2017 in selected developing countries). The total fertility rate in developing countries has decreased from an average of 6.1 children per woman in 1970 to 2.9 in 2017 (excluding China), or 2.6 if China is included. Fertility is highly variable among developing countries, and although the fertility rates in most of these countries have declined, it should be remembered that most still exceed replacement-level fertility. Consequently, the populations in these countries are still increasing. Also, even when fertility rates equal replacement-level fertility, population growth will still continue for some time. To understand why, we now examine the age structure of various countries.

The age structure of a country helps predict future population growth

To predict the future growth of a population, it is important to know its **age structure**, which is the number and proportion of people at each age in a population. The number of males and number of females at each age, from birth to death, are represented in an **age structure diagram**.

The overall shape of an age structure diagram indicates whether the population is increasing, stationary, or shrinking (**FIG. 53-15**). The age structure diagram for less developed countries is shaped like a pyramid. Because the largest percentage of the population is in the pre-reproductive age group (i.e., 0 to 14 years of age), the probability of future population growth is great. A strong **population growth momentum** exists because when all these children mature they will become the parents of the next generation, and this group of parents will be larger than the previous group. Thus, even if the fertility rates in these countries decline to replacement level (i.e., couples have smaller families than their parents did), the

Table 53-4 Fertility Changes in Selected Developing Countries

Country	Total Fertility Rate	
	1960–1965	2017
Bangladesh	6.7	2.3
Brazil	6.2	1.6
China	5.9	1.8
Egypt	7.1	3.3
Guatemala	6.9	2.9
India	5.8	2.3
Kenya	8.1	3.9
Mexico	6.8	2.2
Nepal	5.9	2.3

KEY

Male Female

Figure 53-15 Age structure diagrams

These age structure diagrams for (a) less-developed countries and (b) highly developed countries indicate that less developed regions have a greater percentage of young people than do highly developed countries. As a result, less-developed countries are projected to have greater population growth than are highly developed countries. Adapted from Population Reference Bureau using data from United Nations, World Population Prospects: The 2002 Revision (2003).

population will continue to grow for some time. Population growth momentum can have either a positive value (i.e., the population will grow) or a negative value (i.e., the population will decline). However, it is usually discussed in a positive context, to explain how the future growth of a population is affected by its present age distribution.

In contrast, the more tapered bases of the age structure diagrams of highly developed countries with slowly growing, stable, or declining populations indicate that a smaller proportion of the population will become the parents of the next generation. The age structure diagram of a stable population, one that is neither growing nor shrinking, demonstrates that the number of people at pre-reproductive and reproductive ages are approximately the same. Also, a larger percentage of the population is older—that is, post-reproductive—than in a rapidly increasing population. Many countries in Europe have stable populations. In a population that is shrinking in size, the pre-reproductive age group is smaller than either the reproductive or post-reproductive group. Germany, Russia, and Bulgaria are examples of countries with slowly shrinking populations.

Worldwide, 26% of the human population is younger than age 15. When these people enter their reproductive years, they have the potential to cause a large increase in the growth rate. Even if the birth rate does not increase, the growth rate will increase simply because more people are reproducing.

Most of the world population increase since 1950 has taken place in developing countries as a result of the younger

age structure and the higher-than-replacement-level fertility rates of their populations. In 1950, 66.8% of the world's population was in the developing countries in Africa, Asia (minus Japan), and Latin America. Between 1950 and 2017, the world's population more than doubled in size, but most of that growth occurred in developing countries. As a reflection of this growth, in 2017 the people in developing countries had increased to more than 84% of the world's population. Most of the population increase that will occur during the 21st century will also take place in developing countries, largely the result of their young age structures. These countries, most of which are poor, are least able to support such growth.

Environmental degradation is related to population growth and resource consumption

The relationships among population growth, use of natural resources, and environmental degradation are complex, but we can make two useful generalizations.

First, although the amount of resources essential to an individual's survival may be small, a rapidly increasing population tends to overwhelm and deplete a country's soils, forests, and other natural resources. Thus, **people overpopulation** occurs when the environment is worsening from too many people, even if those people consume few resources per person. People overpopulation is the current problem in many developing nations.

Second, in affluent highly developed nations, individual resource demands are large, far above requirements for survival. **Consumption overpopulation** occurs when people in more affluent nations exhaust resources and degrade the global environment through excessive consumption and "throwaway" lifestyles.

The effects of human populations on the environment are explored in more detail in Chapter 57.

CHECKPOINT 53.6

- What is the reason for the dramatic increase in the world population over the last 200 years?
- **CONNECT** Why is replacement-level fertility greater in developing countries than in highly developed countries? Explain your answer.
- How can a single child born in the United States have a greater effect on the environment and natural resources than a dozen children born in Kenya?

Summary: Focus on Learning Objectives

53.1 Features of Populations (page 1152)

- 1 Define **population density** and **dispersion**, and describe the main types of population dispersion.

- **Population density** is the number of individuals of a species per unit of area or volume at a given time.

Random dispersion Clumped dispersion Uniform dispersion

- Population **dispersion** (spacing) may be **random dispersion** (unpredictably spaced), **clumped dispersion** (clustered in specific parts of the habitat), or **uniform dispersion** (evenly spaced).

53.2 Changes in Population Size (page 1154)

- 2 Explain the four factors (natality, mortality, immigration, and emigration) that produce changes in population size and solve simple problems involving these changes.

- Population size is affected by the average per capita birth rate (b), average per capita death rate (d), and two measures of **dispersal**: average per capita **immigration** rate (i) and average per capita **emigration** rate (e).
- The **growth rate** (r) is the rate of change (increase or decrease) of a population on a per capita basis. On a global scale (when dispersal is not a factor), $r = b - d$. Populations increase in size as long as the average per capita birth rate (**natality**) is greater than the average per capita death rate (**mortality**).
- For a local population (where dispersal is a factor), $r = (b - d) + (i - e)$.

- 3 Define **intrinsic rate of increase** and **carrying capacity**, and explain the differences between J-shaped and S-shaped growth curves.

- **Intrinsic rate of increase** ($r_{\max}$) is the maximum rate at which a species or population could increase in number under ideal conditions.
- Although certain populations exhibit an accelerated pattern of growth known as **exponential population growth** for limited periods of time (the J-shaped curve),

eventually the growth rate decreases to around zero or becomes negative.

- Population size is modified by limits set by the environment. The **carrying capacity** (K) of the environment is the largest population that can be maintained for an indefinite time by a particular environment. **Logistic population growth**, when plotted, shows a characteristic S-shaped curve. Seldom do natural populations follow the logistic growth curve very closely.

53.3 Factors Influencing Population Size (page 1156)

- 4 Contrast the influences of density-dependent and density-independent factors on population size and give examples of each.

- **Density-dependent factors** regulate population growth by affecting a larger proportion of the population as population density rises. Predation, disease, and competition are examples.
- **Density-independent factors** limit population growth but are not influenced by changes in population density. Hurricanes and blizzards are examples.

53.4 Life History Traits (page 1160)

- 5 Contrast semelparous and iteroparous reproduction.

- **Semelparous** species expend their energy in a single, immense reproductive effort. **Iteroparous** species exhibit repeated reproductive cycles throughout their lifetimes.

- 6 Distinguish among species exhibiting an r strategy, those with a K strategy, and those that do not easily fit either category.

- Although many different combinations of life history traits exist, some ecologists recognize two extremes: r strategy and K strategy.
- An r strategy emphasizes a high growth rate. Organisms characterized as **r strategists** often have small body sizes, high reproductive rates, and short **lifespans**, and they typically inhabit variable environments.
- A K strategy maintains a population near the carrying capacity of the environment. Organisms characterized as **K strategists** often have large body sizes, low reproductive rates, and long lifespans, and they typically inhabit stable environments.
- The two strategies oversimplify most life histories. Many species combine r -selected and K -selected traits as well as traits that cannot be classified as either r -selected or K -selected.

- 7 Describe Type I, Type II, and Type III survivorship curves and explain how life tables and survivorship curves indicate mortality and survival.

- A **life table** shows the mortality and survival data of a population or **cohort**—a group of individuals of the same age—at different times during the population's lifespan.
- **Survivorship** is the probability that a given individual in a population or cohort will survive to a particular age. There are three general **survivorship curves**: *Type I survivorship*, in which mortality is greatest in old age; *Type II survivorship*, in which mortality is spread evenly across all age groups; and *Type III survivorship*, in which mortality is greatest among the young.

53.5 Metapopulations (page 1163)

8 Define *metapopulation* and distinguish between source habitats and sink habitats.

- Many species exist as a **metapopulation**, a set of local populations among which individuals are distributed in distinct habitat patches across a **landscape**, which is a large area of terrain (several to many square kilometers) composed of interacting ecosystems.
- Within a metapopulation, individuals occasionally disperse from one local habitat to another by emigration and immigration. **Source habitats** are preferred sites where local reproductive success is greater than local mortality. Surplus individuals disperse from source habitats. **Sink habitats** are lower quality habitats where individuals may suffer death or, if they survive, poor reproductive success. If extinction of a local *sink population* occurs, individuals from a *source population* may recolonize the vacant habitat at a later time.

53.6 Human Populations (page 1164)

9 Summarize the history of human population growth.

- The world population increases by about 100 million people per year and reached 7.5 billion in 2017.
- Although our numbers continue to increase, the per capita growth rate (r) has declined over the past several years, from a peak in 1965 of about 2% per year to a 2017 growth rate of 1.2% per year.
- Scientists who study human **demographics** (human population statistics) project that the world population will become stationary ($r = 0$, or **zero population growth**) by the end of the 21st century.

10 Explain how highly developed and developing countries differ in population characteristics such as infant mortality rate, total fertility rate, replacement-level fertility, and age structure.

- *Highly developed countries* have the lowest birth rates, lowest infant mortality rates, lowest total fertility rates, longest life expectancies, and highest GNI PPP per capita (a measure of the amount of goods and services the average citizen could purchase in the United States) of all countries. *Developing countries* have the highest birth rates, highest infant mortality rates, highest total fertility rates, shortest life expectancies, and lowest GNI PPP per capita.
- The **age structure** of a population greatly influences population dynamics. It is possible for a country to have **replacement-level fertility** and still experience population growth if the largest percentage of the population is in the pre-reproductive years. A young age structure causes a positive **population growth momentum** as the very large pre-reproductive age group matures and becomes parents.

11 Distinguish between people overpopulation and consumption overpopulation.

- Developing countries tend to have **people overpopulation**, in which population increase degrades the environment even though each individual uses few resources.
- Highly developed countries tend to have **consumption overpopulation**, in which each individual in a slow-growing or stationary population consumes a large share of resources, which results in environmental degradation.

Test Your Understanding

Know and Comprehend

1. Population _____ is the number of individuals of a species per unit of habitat area or volume at a given time. (a) dispersion (b) density (c) survivorship (d) age structure (e) demographics
2. The per capita growth rate of a population where dispersal is not a factor is expressed as (a) $i + e$ (b) $b - d$ (c) dN/dt (d) $rN(K - N)$ (e) $(K - N) \div K$
3. The maximum rate at which a population could increase under ideal conditions is known as its (a) total fertility rate (b) survivorship (c) intrinsic rate of increase (d) doubling time (e) age structure
4. When r is a positive number, the population size is (a) stable (b) increasing (c) decreasing (d) either increasing or decreasing, depending on interference competition (e) either increasing or stable, depending on whether the species is semelparous
5. In a graph of population size versus time, a J-shaped curve is characteristic of (a) exponential population growth (b) logistic population growth (c) zero population growth (d) replacement-level fertility (e) population growth momentum
6. The largest population that can be maintained by a particular environment for an indefinite period is known as a (a) semelparous population (b) population undergoing exponential growth (c) metapopulation (d) population's carrying capacity (e) source population
7. Giant bamboos live many years without reproducing, then send up a huge flowering stalk and die shortly thereafter. Giant bamboo is therefore an example of (a) iteroparity (b) a source population (c) a metapopulation (d) an r strategist (e) semelparity
8. Predation, disease, and competition are examples of _____ factors. (a) density-dependent (b) density-independent (c) survivorship (d) dispersal (e) semelparous
9. _____ competition occurs within a population, and _____ competition occurs among populations of different species. (a) Interspecific; intraspecific (b) Intraspecific; interspecific (c) Type I survivorship; Type II survivorship (d) Interference; exploitation (e) Exploitation; interference
10. A highly developed country has a (a) long doubling time (b) low infant mortality rate (c) high GNI PPP per capita (d) a and b (e) a, b, and c
11. The continued growth of a population with a young age structure, even after its fertility rate has declined, is known as (a) population doubling (b) iteroparity (c) population growth momentum (d) r selection (e) density dependence
12. Which of the following patterns of cars parked along a street is an example of uniform dispersion? (a) five cars

Apply and Analyze

- parked next to one another in the middle, leaving two empty spaces at one end and three empty spaces at the other end (b) five cars parked in this pattern: car, empty space, car, empty space, and so on (c) five cars parked in no discernible pattern, sometimes having empty spaces on each side and sometimes parked next to another car
13. A female elephant bears a single offspring every two to four years. Based on this information, which survivorship curve do you think is representative of elephants? Explain your answer.

Evaluate and Synthesize

14. Explain why the population size of a species that competes by interference competition is often near the carrying capacity, whereas the population size of a species that competes by exploitation competition is often greater than or below the carrying capacity.
15. **EVOLUTION LINK** In developing his scientific theory of evolution by natural selection, Charles Darwin considered four main observations: heritable variation among individuals in a population, overproduction of offspring, limits on population growth, and differential reproductive success. Compare how these observations may apply to populations that tend to fit the concepts of *r* selection and *K* selection.
16. **INTERPRET DATA** In Bolivia, 35% of the population is younger than age 15, and 5% is older than 65. In Austria, 14% of the population is younger than 15, and 18% is older than 65. Which country will have the highest growth rate over the next two decades? Explain your answer.
17. **INTERPRET DATA** The 2017 population of the Netherlands was 17.1 million, and its land area is 15,768 square miles. The 2017 population of the United States was 325.4 million, and its land area is 3,717,796 square miles. Which country has the greater population density?
18. **INTERPRET DATA** The population of India in 2017 was 1,352.6 million, and its growth rate was 1.4% per year. Calculate the 2018 population of India.
19. **INTERPRET DATA** The world population in 2017 was 7.5 billion, and its annual growth rate was 1.2%. If the birth rate was 20 per 1000 people in the year 2017, what was the death rate, expressed as number per 1000 people?
20. **INTERPRET DATA** Consider the age structure diagrams for counties (a) and (b). Which diagram is consistent with negative growth momentum? Why?
21. **SCIENCE, TECHNOLOGY, AND SOCIETY** In what ways has technology contributed to consumption overpopulation? Can you propose some applications of technology that might help alleviate its effects?

54 Community Ecology

In Chapter 53 we examined the dynamics of populations. In the natural world, most populations are part of a **community**, which consists of an association of populations of different species. These populations and species live and interact, directly and indirectly with each other, in the same place at the same time. The definition for *community* is deliberately broad because it refers to ecological categories that vary greatly in size, lack precise boundaries, and are rarely completely isolated.

Smaller communities nest within larger communities. A mangrove forest is a community, but so are the interlacing roots that support each tree (see photograph). Mangrove roots, anchored in sediment made up of sand and peat, are breeding grounds and nurseries for crabs, shrimp, and many commercially important fish. Blue crabs, lizards, and turtles feed on insects, algae, and dead animal material. Small mammals scurry among the roots, and manatees and alligators find shelter from the tropical sun. Mangrove root surfaces are home to invertebrates, algae, bacteria, archaea, and fungi, which provide nutrients for other organisms. Mangroves also filter excess nutrients and some toxic pollutants from the water.

Organisms exist in an abiotic (nonliving) environment that is as essential to their lives as their interactions with one another. Minerals, air, water, and sunlight are just as much a part of a bat's environment, for example, as the flowers it pollinates and depends on for nectar and insects. A biological community and its abiotic environment together compose an **ecosystem**. Like communities, ecosystems are broad entities that refer to ecological units of various sizes.

In this chapter, we focus on living communities. We explore some of the challenges in understanding common patterns and processes that govern communities. The abiotic components of ecosystems, including energy flow and trophic structure (feeding relationships), nutrient cycling, and climate, are considered in Chapter 55.

KEY CONCEPTS

- 54.1** A community consists of populations that live in the same place at the same time. Community ecologists focus on questions concerning the number of species, the relative abundance of each species, interactions among species, and resistance of the community to environmental disturbances (natural and human-made).
- 54.2** Both dominant species and keystone species have community-wide effects on energy flow and community structure: dominant species because of their large biomass or abundance, and keystone species despite their relatively small biomass or abundance.
- 54.3** Factors that influence community diversity include the number, variety, and abundance of species. Field experiments with plants beginning in the 1990s suggest that more diverse communities have a greater stability, or resistance to change.
- 54.4** Most ecologists think that communities are loose associations of organisms that have similar environmental requirements and therefore live together in the same environment. Following a disturbance, communities undergo succession from pioneer communities to mature communities.

54.1 Community Structure and Functioning

LEARNING OBJECTIVES

- 1 Define *ecological niche* and distinguish between an organism's fundamental niche and its realized niche.
- 2 Define *competition* and distinguish between interspecific and intraspecific competition.
- 3 Summarize the concepts of the competitive exclusion principle, resource partitioning, and character displacement.

Jardin Lautaret/Station Alpine Joseph Fourier

(a) *Laretia acaulis* plants increase the survival rate of certain nearby plants at 2800 m (9100 ft) in the Andes Mountains of Chile. The effect is less pronounced at higher elevations.

- 4 Define *predation* and describe the effects of natural selection on predator–prey relationships.
- 5 Distinguish among mutualism, commensalism, and parasitism, and give examples of each.

Communities exhibit characteristic properties that populations lack. These properties, known collectively as *community structure* and *community functioning*, include the number and types of species present, the relative abundance of each species, the interactions among different species, community resilience to disturbances, energy and nutrient flow throughout the community, and productivity. **Community ecology** is the description and analysis of patterns and processes within the community. Finding common patterns and processes in a wide variety of communities—for example, a pond community, a pine forest community, and a human gut community—helps ecologists understand community structure and functioning.

Communities are exceedingly difficult to study because a large number of individuals of many different species interact with one another and are interdependent in a variety of ways. Species compete with one another for food, water, living space, and other resources. (Used in this context, a *resource* is anything from the environment that meets needs of a particular species.) Some organisms kill and eat other organisms, cause disease, or alter their immediate surroundings to inhibit competing life.

Some species form intimate, complex associations with one another, whereas other species seem only remotely connected. Certain species interact in positive ways in a process known as **facilitation**, which modifies and enhances the local environment for other species. For example, alpine plants in harsh mountain environments grow faster and larger and reproduce more successfully when certain other plants are growing nearby (FIG. 54-1).

(b) Field mouse-ear chickweed (*Cerastium arvense*) plants were planted and grown within (red) and outside (blue) clumps of *Laretia acaulis*.

(c) Alpine barley (*Hordeum comosum*) plants were planted and grown within (red) and outside (blue) clumps of *Laretia acaulis*.

Figure 54-1 Facilitation in alpine communities

Also, each organism plays one of three main roles in community life: producer, consumer, or decomposer. Unraveling the many positive and negative, direct and indirect interactions of organisms living together as a community is one of the goals of community ecologists.

Community interactions are complex and often not readily apparent

During the late 1990s, an intricate relationship emerged among acorn production, white-footed mice, deer, gypsy moth population growth, and the potential occurrence of Lyme disease in humans (FIG. 54-2). Large-scale experiments conducted in oak forests of the northeastern United States linked bumper acorn crops, which occur every three to four years, to booming mouse populations (the mice eat the acorns). Because the mice also eat gypsy moth pupae, high acorn conditions also lead to low populations of gypsy moths. This outcome helps the oaks because gypsy moths cause serious defoliation. However, abundant acorns also attract tick-bearing deer to oak forests. The ticks' hungry offspring feed on the mice, which often carry the Lyme disease-causing bacterium. The bacterium infects the maturing ticks and, in turn, spreads to humans who are bitten by affected ticks. In 2006, scientists concluded that it is possible to predict which years pose the greatest potential threat of Lyme disease to humans based on when oaks are most productive. They determined that the risk of Lyme disease is greater two years following a bumper acorn crop than in other years.

Within a community, no species exists independently of other species. As the preceding example shows, the populations of a community interact with and affect one another through complex networks that are not always obvious. Three main types of interactions occur among species in a community: competition, predation, and symbiosis. Before we address these interactions, however, we need to examine the way of life of a given species in its community.

The niche is a species' ecological role in the community

Every species is thought to have its own ecological role within the structure and function of a community; we call this role its **ecological niche**. Although the concept of ecological niche has been in use in ecology since early in the 20th century, Yale ecologist G. E. Hutchinson first described in 1957 the multidimensional nature of the niche that is accepted today. An ecological niche takes into account all biotic and abiotic aspects (and combinations) of the species' existence, that is, all the physical, chemical, and biological factors that the species needs to survive, remain healthy, and reproduce. A niche includes the local environment in which a species lives, its **habitat**. A niche also encompasses what a species eats, what eats it, and the organisms with which the species has a relationship (positive, negative, or neutral). Ecologists also consider how each species interacts with and is influenced by the abiotic components of its environment, such as light, temperature, and moisture. The

Figure 54-2 Connections to the size of an acorn crop

When there is a bumper crop of acorns, more mice survive and breed in winter, and more deer are attracted to oak forests. Both mice and deer are hosts of ticks that may carry the Lyme disease bacterium to humans. Abundant mice also reduce gypsy moth populations, thereby improving the health of forest trees.

niche thus represents the totality of adaptations by a species to its environment, its use of resources, and the lifestyle to which it is suited. Clearly, a complete description of an organism's ecological niche involves many dimensions and is difficult to define precisely. For these reasons, ecologists usually confine their studies to one or a few niche variables, such as feeding behaviors or ability to tolerate temperature extremes.

The ecological niche of a species is far broader hypothetically than in actuality. A species is usually capable of using much more of its environment's resources or of living in a wider assortment of habitats than it actually does. The potential ecological niche of a species, or the conditions it can theoretically live in without competitors, is its **fundamental niche**. Various factors, such as competition with other species, may exclude it from part of this fundamental niche. Thus, the lifestyle that a species actually pursues and the resources it actually uses make up its **realized niche**.

An example may help make this distinction clear. The green anole, a lizard native to Florida and other southeastern states, perches on trees, shrubs, walls, or fences during the day, waiting for insect and spider prey (FIG. 54-3a). In the past, these little lizards were widespread in Florida. Several decades ago, however, a related species, the brown anole introduced from Cuba into

southern Florida, spread northward up the Florida peninsula and quickly became common (FIG. 54-3b). Suddenly, the green anoles became rare, apparently driven out of their habitat by competition from the slightly larger brown anoles. Careful investigation, however, disclosed that green anoles were still around. They were now confined largely to the vegetation in wetlands and to the foliated crowns of trees, where they were less easily seen.

The habitat portion of the green anole's fundamental niche includes the trunks and crowns of trees, exterior house walls, and many other locations. Once the brown anoles became established in the green anole habitat, they drove the green anoles from all but wetlands and tree crowns; competition between the two species shrank the green anole's realized niche (FIGS. 54-3c and d). Because communities consist of numerous species, many of which compete to some extent, the interactions among them produce the realized niche of each species.

Limiting resources restrict the ecological niche of a species A species' structural, physiological, and behavioral adaptations determine its tolerance for environmental extremes. If any feature of an environment lies outside the bounds of its tolerance, the species cannot live there. Just as you would not expect to find a

cactus living in a pond, you would not expect water lilies in a desert.

The environmental factors that actually determine a species' ecological niche are difficult to identify. For this reason, the concept of ecological niche is largely abstract, although some of its dimensions can be experimentally determined. Any environmental resource that, because it is scarce or unfavorable, tends to restrict the ecological niche of a species is called a **limiting resource**.

Most of the limiting resources that have been studied are simple variables, such as the soil's mineral content, temperature extremes, and precipitation amounts. Such investigations have disclosed that any factor, either exceeding the tolerance of a species or present in quantities smaller than the required minimum, limits the presence of that species in a community. By their interaction, such factors help define the ecological niche for a species.

Limiting resources may affect only part of an organism's life cycle. For example, although adult blue crabs live in fresh or slightly brackish water, they do not become permanently established in such areas because

(a) Green anole lizard with dragonfly prey. The green anole (*Anolis carolinensis*) is the only anole species native to North America. Males are about 12.5 cm (5 in.) long; females are slightly smaller. (Photographed on Jefferson Island, Louisiana.)

(b) The brown anole (*A. sagrei*), which is 15.2 cm (6 in.) long, was introduced to Florida. It is native to Cuba and the Bahamas.

(c) Positions of the two species along a single niche dimension (habitat). Species 1 represents the green anole, and Species 2 represents the brown anole. The fundamental niches of the two lizards overlap.

(d) The brown anole outcompetes the green anole in the area where their niches overlap, restricting the niche of the green anole.

Figure 54-3 Effect of competition on an organism's realized niche

their larvae (immature forms) require salt water. Similarly, the ring-necked pheasant, a popular game bird native to Eurasia, has been widely introduced in North America but has not become established in the southern United States. The adult birds do well there, but the eggs do not develop properly in the warmer southern temperatures.

Biotic and abiotic factors influence a species' ecological niche In the 1960s, U.S. ecologist Joseph H. Connell investigated biotic and abiotic factors that affect the distribution of two barnacle species in the rocky *intertidal zone* along the coast of Scotland. The intertidal zone is a challenging environment, and organisms in the intertidal zone must tolerate exposure to the drying air during low tides. Barnacles are sessile crustaceans whose bodies are covered by a shell of calcium carbonate (see Fig. 31-29a). When the shell is open, feathery appendages extend to filter food from the water.

Along the coast of Scotland, more adults of one barnacle species, *Semibalanus balanoides* (formerly called *Balanus balanoides*), are attached on lower rocks in the intertidal zone than are adults of the other species, *Chthamalus stellatus* (FIG. 54-4). The distributions of the two species do not overlap, although immature larvae of both species live together in the intertidal zone. Connell manipulated the two populations to determine what factors were affecting their distribution. When he removed *Chthamalus* from the upper rocks, *Semibalanus* barnacles did not expand into the vacant area.

Connell's experiments showed that *Chthamalus* is more resistant than *Semibalanus* to desiccation when the tide retreats. However, when Connell removed *Semibalanus* from the lower rocks, *Chthamalus* expanded into the lower parts of the intertidal zone. The two species compete for space, and *Semibalanus*, which is larger and grows faster, outcompetes the smaller *Chthamalus* barnacles.

Competition among barnacle species for the limiting resource of living space was one of the processes that Connell's research demonstrated. We now examine other aspects of competition that various ecologists have demonstrated in both laboratory and field studies.

Competition is intraspecific or interspecific

Competition occurs when two or more individuals attempt to use the same essential resource, such as food, water, shelter, living space, or sunlight. Because resources are often in limited supply in the environment, their use by one individual decreases the amount available to others (TABLE 54-1). If a tree in a dense forest grows taller than surrounding trees, for example, it absorbs more of the incoming sunlight. Less sunlight is therefore available for nearby trees that are shaded by the taller tree. Competition occurs among individuals within a population (**intraspecific competition**) or between different species (**interspecific competition**). (Intraspecific competition was discussed in Chapter 53.)

Figure 54-4 Abiotic and biotic factors that affect barnacle distribution

After J.H. Connell, "The Influence of Interspecific Competition and Other Factors on the Distribution of the Barnacle *Chthamalus stellatus*," *Ecology*, Vol. 42 (1961).

(a) Species of barnacles belonging to two genera, *Chthamalus* and *Semibalanus*, grow in the intertidal zone of a rocky shore in Scotland.

(b) When *Chthamalus* individuals were experimentally removed, *Semibalanus* individuals did not expand into their section of the rock.

(c) When *Semibalanus* individuals were experimentally removed, *Chthamalus* individuals spread into the empty area.

Table 54-1 Ecological Interactions among Species

Interaction	Effect on Species 1	Effect on Species 2
Competition between species 1 and species 2	Harmful	Harmful
Predation of species 2 (prey) by species 1 (predator)	Beneficial	Harmful
Symbiosis		
Mutualism of species 1 and species 2	Beneficial	Beneficial
Commensalism of species 1 with species 2	Beneficial	No effect
Parasitism by species 1 (parasite) on species 2 (host)	Beneficial	Harmful

Ecologists traditionally assumed that competition is the most important determinant of both the number of species found in a community and the size of each population. Today ecologists recognize that competition is only one of many interacting biotic and abiotic factors that affect community structure. Furthermore, competition is not always a straightforward, direct interaction. Several kinds of flowering plants, for example, live in a young pine forest and presumably compete with the conifers for such resources as soil moisture and soil minerals. Their relationship, however, is more complex than simple competition. The flowers produce nectar that is consumed by some insect species that also prey on needle-eating insects, thereby reducing the number of insects feeding on pines. It is therefore difficult to assess the overall effect of flowering plants on pines. If the flowering plants were removed from the community, would the pines grow faster because they were no longer competing for necessary resources? Or would the increased presence of needle-eating insects (caused by fewer predatory insects) inhibit pine growth?

Short-term experiments in which one competing plant species is removed from a forest community have often demonstrated an improved growth for the remaining species. However, very few studies have tested the long-term effects on forest species of removing a single competing species. These long-term effects may be subtle, indirect, and difficult to ascertain; they may lessen or negate the short-term effects of competition for resources.

Competition between species with overlapping niches may lead to competitive exclusion When two species are similar, as are the green and brown anoles or the two species of barnacles, their fundamental niches may overlap. However, based on experimental and modeling work, many ecologists think that no two species indefinitely occupy the same niche in the same community. According to the **competitive exclusion principle**, it is hypothesized that one species excludes another from its niche as a result of interspecific competition. Although it is possible for species to compete for some necessary resource without being total competitors, two species with absolutely identical ecological niches cannot coexist. Coexistence occurs, however, if the overlap between the two niches is reduced. In the lizard example, direct competition between the two species was reduced as the brown anole excluded the green anole from most of its former habitat.

The initial evidence that interspecific competition contributes to a species' realized niche came from a series of laboratory experiments by Russian biologist Georgyi F. Gause in the 1930s. In one study Gause grew populations of two species of protozoa, *Paramecium aurelia* and the larger *P. caudatum*, in controlled conditions (FIG. 54-5). When grown in separate test tubes—that is, in the absence of the second species—the population of each species quickly increased to a level imposed by the resources and remained there for some time thereafter. When grown together, however, only *P. aurelia* thrived, whereas *P. caudatum* dwindled and eventually died out. Under different sets of culture conditions, *P. caudatum* prevailed over *P. aurelia*. Gause interpreted these results to mean that although one set of conditions favored one species, a different set favored the other. Nonetheless, because both species were so similar, in time one or the other would eventually triumph. Similar experiments with competing species of fruit flies, mice, beetles, and annual plants have supported Gause's results: one species thrives, and the other eventually dies out.

Thus, competition has adverse effects on species that use a limited resource and may result in competitive exclusion of one or more species. It therefore follows that over time natural selection should favor individuals of each species that avoid or reduce competition for environmental resources. Reduced competition among coexisting species as a result of each species' niche differing from the others in one or more ways is called **resource partitioning**. Resource partitioning is well-documented in animals; studies in tropical forests of Central America and South America demonstrate little overlap in the diets of fruit-eating birds, primates, and bats that coexist in the same habitat. Although fruits are the primary food for several hundred bird, primate, and bat species, the wide variety of fruits available has allowed fruit eaters to specialize, which reduces competition.

Resource partitioning may also include timing of feeding, location of feeding, nest sites, and other aspects of a species' ecological niche. Princeton ecologist Robert MacArthur's study of five North American warbler species is a classic example of resource partitioning (FIG. 54-6). Although initially the warblers' niches seemed nearly identical, MacArthur found that individuals of each species spend most of their feeding time in different portions of the spruces and other conifer trees they frequent. They also move in different directions through the canopy, consume different combinations of insects, and nest at slightly different times.

Difference in root depth is an example of resource partitioning in plants. For example, three common annuals found in certain abandoned fields are smartweed, Indian mallow, and bristly foxtail. Smartweed roots extend deep into the soil, Indian mallow roots grow to a medium depth, and bristly foxtail roots are shallow. This difference reduces competition for the same soil resources—water and minerals—by allowing the plants to exploit different portions of the resource.

Character displacement is an adaptive consequence of interspecific competition Sometimes populations of two similar species occur together in some locations and separately in others. Where their geographic distributions overlap, the two species tend to differ more in their structural, ecological, and behavioral characteristics than they do where

Key Experiment

Can competitive exclusion be demonstrated in the laboratory under controlled conditions?

HYPOTHESIS: When two species of paramecia (ciliated protozoa) are grown together in a mixed culture, one species outcompetes the other.

EXPERIMENT: Gause grew two species of paramecia, both separately and together.

RESULTS AND CONCLUSION: The top and middle graphs show how each species of *Paramecium* flourishes when grown alone. The bottom graph shows how they grow together, in competition with each other. In a mixed culture, *P. aurelia* outcompetes *P. caudatum*, resulting in competitive exclusion.

SOURCE: Adapted from G.F. Gause, *The Struggle for Existence* (Williams and Wilkins, Baltimore, 1934).

Figure 54-5 G.F. Gause's classic experiment on interspecific competition

PREDICT What would happen to the two competing cultures shown in the bottom graph if a medium containing a nutrient that could be metabolized only by *P. caudatum* replaced the existing growth medium at day 6?

each occurs in separate geographic areas. Such divergence in traits in two similar species living in the same geographic area is known as **character displacement**. Biologists think that character displacement reduces competition between two species because their differences give them somewhat different ecological niches in the same environment.

There are several well-documented examples of character displacement between two closely related species. The flowers of two *Solanum* species in Mexico are quite similar in

Figure 54-6 Resource partitioning

Each warbler species spends at least half its foraging time in its designated area of a spruce tree, thereby reducing the competition among warbler species. After R.H. MacArthur, "Population Ecology of Some Warblers of Northeastern Coniferous Forests," *Ecology*, Vol. 39 (1958).

areas where either one or the other occurs. However, where their distributions overlap, the two species differ significantly in flower size and are pollinated by different kinds of bees. In other words, character displacement reduces interspecific competition, in this case for the same animal pollinator.

The bill sizes of Darwin's finches provide another example of character displacement (**FIG. 54-7**). On large islands in the Galápagos where the medium ground finch (*Geospiza fortis*) and the small ground finch (*G. fuliginosa*) occur together, their bill depths are distinctive. *Geospiza fuliginosa* has a smaller bill depth that enables it to crack small seeds, whereas *G. fortis* has a larger bill depth that enables it to crack medium-sized seeds. However, *G. fortis* and *G. fuliginosa* also live on separate islands. Where the two species live separately, bill depths are about the same intermediate size, perhaps because there is no competition from the other species.

Although these examples of the coexistence of similar species are explained in terms of character displacement, the character displacement hypothesis has been demonstrated in nature in only a few instances. In 2006, Peter and Rosemary Grant, who had studied Darwin's finches in the Galápagos Islands since the 1970s, reported in the journal *Science* another example of character displacement in Darwin's finches. The medium ground finch (*G. fortis*) originally lived on one of the small Galápagos islands by itself. Different *G. fortis* individuals had varying beak sizes that allowed them to eat small, medium, or

Key Experiment

Can character displacement be demonstrated in the wild?

HYPOTHESIS: Two species of finches are more different where they occur together than where they occur separately.

EXPERIMENT: Two species of Darwin's finches in the Galápagos were observed on islands where they occur separately and on an island where they exist together. Bill depth (a), which varies considerably in the two species, was measured in the different environments.

RESULTS AND CONCLUSION: (b) Where the two species are found on the same island (Santa Cruz), *G. fuliginosa* (red) has a smaller average bill depth than *G. fortis* (blue). Where they occur on separate islands (c, on Daphne Major, and d, on Los Hermanos), the average bill depths of each are similar. Thus, they illustrate character displacement.

SOURCE: After D. Lack, *Darwin's Finches* (Cambridge University Press, Cambridge, 1947).

Figure 54-7 Character displacement

PREDICT If *G. fuliginosa* were removed from the shared island, would you expect the beaks of the *G. fortis* population to change over time? In what way?

large seeds. However, in recent years the large ground finch (*G. magnirostris*) colonized the island and began to compete with the medium ground finch for the larger seeds. A severe drought reduced the seed supply, putting additional pressure on the medium finch population. In response, the medium ground finch's beak quickly diverged, becoming significantly smaller in length, depth, and width on average than it had been. The altered population of medium ground finches now consumes small seeds almost exclusively; their small beaks cannot crack the larger seeds preferred by the large ground finch.

Natural selection shapes the bodies and behaviors of both predator and prey

Predation is the consumption of one species, the *prey*, by another, the *predator* (see Table 54-1). Predation includes animals eating other animals as well as animals eating plants (*herbivory*). Predation has resulted in an evolutionary “arms race,” with the evolution of predator strategies (more efficient ways to catch prey) and prey strategies (better ways to escape the predator). A predator that is more efficient at catching prey exerts a strong selective force on its prey. Over time, adaptations that reduce the probability of being captured may evolve in the prey species. In turn, these adaptations exert a strong selective force on the predator. This type of interdependent evolution of two interacting species is known as **coevolution** (see discussion of coevolution in Chapter 37).

We now consider several adaptations related to predator–prey interactions, including predator strategies (pursuit and ambush) and prey strategies (plant defenses and animal defenses). Keep in mind as you read these descriptions that such strategies are not “chosen” by the respective predators or prey. New traits arise randomly in a population as a result of genetic changes. Some new traits are beneficial, some are harmful, and others have no effect. Beneficial strategies, or traits, persist in a population because such characteristics make the individuals that have them well suited to thrive and reproduce. In contrast, characteristics that make the individuals that have them poorly suited to their environment tend to disappear in a population.

Pursuit and ambush are two predator strategies

A brown pelican sights its prey—a fish—while in flight. Less than 2 seconds after diving into the water at a speed as great as 72 km/h (45 mph), it has its catch. Orcas, formerly known as killer whales, hunt in packs and often herd salmon or tuna into a cove so that they are easier to catch. Any trait that increases hunting efficiency, such as the speed of brown pelicans or the intelligence and cooperative behavior of orcas, favors predators that pursue their prey. Because these carnivores must process information quickly during the pursuit of prey, their brains are generally larger, relative to body size, than those of the prey they pursue.

Ambush is another effective way to catch prey. The yellow crab spider, for example, is the same color as the white or yellow flowers on which it hides (FIG. 54-8). This camouflage keeps unwary insects that visit the flower for nectar from noticing the spider until it is too late. It also fools birds that prey on the crab spider.

Predators that *attract* prey are particularly effective at ambushing. For example, a diverse group of deep-sea fishes

Zoltan Pataki/Shutterstock.com

called anglerfish possess rodlike bioluminescent lures close to their mouths to attract prey.

Chemical protection is an effective plant defense against herbivores Plants cannot escape predators by fleeing, but they have several physical and chemical adaptations that protect them from being eaten. The presence of spines, thorns, tough leathery leaves, or even thick wax on leaves discourages foraging herbivores from grazing. Other plants produce an array of protective chemicals that are unpalatable or even toxic to herbivores. The active ingredients in such plants as marijuana and tobacco affect hormone activity and nerve, muscle, liver, and kidney functions and may discourage foraging by herbivores. Interestingly, many of the chemical defenses in plants are useful to humans. India's neem tree, for example, contains chemicals effective against more than 100 species of herbivorous insects, mites, and nematodes. Nicotine from tobacco, pyrethrum from chrysanthemum, and rotenone from the derris plant are other examples of chemicals extracted and used as insecticides.

Milkweeds are an excellent example of the biochemical coevolution between plants and herbivores (FIG. 54-9). Milkweeds produce alkaloids and cardiac glycosides, chemicals that are poisonous to all animals except a small group of insects. The ability to either tolerate or metabolize the milkweed toxins has evolved in these insects. They eat milkweeds and avoid competition from other herbivorous insects because few others tolerate milkweed toxins. Predators also learn to avoid these insects, which accumulate the toxins in their tissues and therefore become toxic themselves. The black, white, and yellow coloration of the monarch caterpillar, a milkweed feeder, clearly announces its toxicity to predators that have learned to associate bright colors with illness. Conspicuous colors or patterns, which advertise a species' unpalatability to potential predators, are known as **aposematic coloration** (pronounced "ap'-uh-suh-mat'-ik"; from the Greek *apo*, "away," and *semat*, "a mark or sign"), or **warning coloration**.

Animal prey possess various defensive adaptations to avoid predators Many animals, such as prairie voles and woodchucks, flee from predators by running to their underground burrows. Others have mechanical defenses, such as the barbed quills of a porcupine and the shell of a pond turtle. To discourage predators, the porcupine fish inflates itself to three times its normal size by pumping water into its stomach (see Fig. 32-14a). Some animals live in groups, such as a herd of antelope, colony of honeybees, school of anchovies, or flock of pigeons. Because a group has so many eyes, ears, and noses watching, listening, and smelling for predators, this social behavior decreases the likelihood of a predator catching any one of them unaware.

Chemical defenses are also common among animal prey. The South American poison arrow frog (*Dendrobates*) stores poison in its skin. (These frogs obtain the toxins from ants and other insects in their diet.) The frog's bright aposematic coloration prompts avoidance by experienced predators (see Fig. 32-18a). Snakes and other animals that have tried once to eat a poisonous frog do not repeat their mistake! Other examples of aposematic coloration occur in the striped skunk, which sprays acrid chemicals from its anal glands, and the bombardier beetle, which spews harsh chemicals at potential predators (see Fig. 7-8).

Some animals have **cryptic coloration**, colors or markings that help them hide from predators by blending into their physical surroundings. Certain caterpillars resemble twigs so closely that you would never guess that they were animals unless they moved. Pipefish are slender green fish that are almost perfectly camouflaged in green eelgrass. Leaf-tailed geckos in southern Madagascar resemble dead leaves or mossy bark, depending on the species (FIG. 54-10). Such cryptic coloration has been preserved and accentuated by means of natural selection. Predators are less likely to capture animals with cryptic coloration than other animals. Such animals are therefore more likely to live to maturity and produce offspring that also carry the genes for cryptic coloration.

Greg Dimijian/Science Source

Figure 54-10 Cryptic coloration

The mossy leaf-tailed gecko (*Uroplatus sikorae*) hunts for insects by night and sleeps pressed against a tree branch by day. It is virtually invisible when it sleeps (look closely to see its head and front foot). Photographed in a rain forest in southern Madagascar.

Sometimes a defenseless species (a *mimic*) is protected from predation by its resemblance to a species that is dangerous in some way (a *model*). Such a strategy is known as **Batesian mimicry**. Many examples of this phenomenon exist. For example, a harmless scarlet king snake looks so much like a venomous coral snake that predators may avoid it (FIG. 54-11). Interestingly,

the range of the scarlet king snake extends far beyond that of the coral snake. In an area where coral snakes do not occur, having the coloration of the model confers no special advantage to the king snake and may be harmful, triggering natural selection. This seems to be the case: scientists have reported that scarlet king snake populations located far from coral snakes have undergone natural selection and look less like their model.

In **Müllerian mimicry**, two or more different species (*co-models*), all of which are poisonous, harmful, or distasteful, come to resemble one another during the course of evolution. Although their harmfulness protects them as individual species, their similarity in appearance works as an adaptive advantage because potential predators more easily learn a single common aposematic coloration. Scientists hypothesize that viceroy and monarch butterflies are an example of Müllerian mimicry. Researchers have found that fewer butterflies of either species are eaten and more individuals survive to reproduce.

Symbiosis involves a close association between species

Symbiosis is any intimate relationship or association between members of two or more species. Usually, symbiosis involves one species living on or in another species. The partners of a symbiotic relationship, called **symbionts**, may benefit from, be unaffected by, or be harmed by the relationship (see Table 54-1). Examples of symbiosis occur across all the domains and kingdoms of life. Most of the millions of symbiotic associations are products of coevolution. Symbiosis takes three forms: mutualism, commensalism, and parasitism.

Benefits are shared in mutualism **Mutualism** is a symbiotic relationship in which both partners benefit. Mutualism is either obligate (essential for the survival of both species) or facultative (either partner can live alone under certain conditions).

Inquiring About

The Human Microbiota: Our Many Symbionts

We humans are much more complex than you might imagine, particularly when we identify and count our microbiota. Tens (or even hundreds) of trillions of bacteria, fungi, archaea, protists, and viruses colonize the human body. Biologists have yet to agree on a total count for our symbionts. Currently, researchers estimate that our bacteria count alone surpasses the number of our human cells (about 30 trillion for an adult male) and likely outnumbers them by a ratio of more than 3:1. These figures do not take into account the various species of worms and the many arthropod parasites we may carry.

The majority of microbiota colonize our gastrointestinal tract, but distinct, diverse populations also reside on our skin and on or within our mouth, genitourinary tract, lungs, and body fluids. Biologists now understand that our microbiota play an extremely significant role both in maintaining our health and in preventing disease. Our microbiota support digestion, improve nutrition, help regulate metabolism and the immune system, and repel pathogen invasions. The symbiotic relationships between our microbiota and our human cells are not always mutual or commensal, however.

When the normal habitats, or balance, of the symbiont ecosystem is disturbed, or altered, some of our microbiotic relationships

can contribute to or cause disease. Crohn's disease, irritable bowel syndrome, chronic periodontitis, obesity, cancer, and bacterial vaginosis are examples. Antibiotic-associated diarrhea is a disturbance in which abrupt changes occur in the gut community composition. Many members of the community are killed by antibiotics, providing niches for opportunistic pathogens and/or overgrowth of remaining species of bacteria. *Clostridium difficile*, for example, is responsible for serious and often long-term diarrhea after a course of antibiotics. In extreme cases, the colon can become inflamed, resulting in serious infection and even death.

Recent advances in gene sequencing, genomics, and associated technologies, along with the growing research in microbial ecology, continue to rapidly expand our understanding of how we humans and our symbionts have coevolved. Biologists are now able to quickly survey our microbiota to answer many species diversity questions. Research is complicated not only by the incredible diversity of the microbiota, but also by many variations between individual humans and composition changes of communities at

different stages of our lives. Biologists are now constructing a multifaceted view of how the microbial community works synergistically among species, including humans. Exploration and development of new methods that target, or deliberately manipulate, our microbiota will benefit our future health and survival.

3 μ m

Colorized SEM of bacteria on the end of an endoscope after a colonoscopy. This is a very small sample of the many types of bacteria that inhabit the colon.

The association between *nitrogen-fixing bacteria* of the genus *Rhizobium* and legumes (plants such as peas, beans, and clover) is an example of mutualism (see Fig. 55-9). Nitrogen-fixing bacteria, which live inside nodules on the roots of legumes, supply the plants with most of the nitrogen they require to manufacture such nitrogen-containing compounds as chlorophylls, proteins, and nucleic acids. The legumes supply sugars and other energy-rich organic molecules to their bacterial symbionts.

Another example of mutualism is the association between reef-building animals and dinoflagellates called **zooxanthellae**. These symbiotic protists live inside cells of the coral polyp (the coral forms a vacuole around the algal cell), where they photosynthesize and provide the animal with carbon and nitrogen compounds as well as oxygen (FIG. 54-12). Calcium carbonate skeletons form around the coral bodies much faster when zooxanthellae are present; their faster growth helps the corals dominate their location on a reef. The corals, in turn, supply the zooxanthellae with waste products such as ammonia, which the algae use to make nitrogen compounds for both partners. (Also see the discussion in Chapter 31 and Fig. 31-6.)

Mycorrhizae are mutualistic associations between fungi and the roots of plants. The association is common; biologists think that nearly 90% of all plant species have mycorrhizae. The fungus, which grows around and into the root as well as into the surrounding soil, absorbs essential minerals, especially phosphorus,

Figure 54-12 Mutualism

The greenish brown specks in these polyps of stony coral (*Pocillopora*) are zooxanthellae, dinoflagellates that live symbiotically within the coral's translucent cells and supply the coral with carbon and nitrogen compounds. In return, the coral provides the zooxanthellae with nitrogen in the form of ammonia.

from the soil and provides them to the plant. In return, the plant provides the fungus with organic molecules produced by photosynthesis. Plants grow more vigorously in the presence of mycorrhizal fungi (see Figs. 29-19 and 36-11), and they better tolerate

environmental stressors such as drought and high soil temperatures. Indeed, some plants cannot maintain themselves under natural conditions if the fungi with which they normally form mycorrhizae are not present.

Humans and bacteria also share mutualistic relationships. Recall that the term **microbiome** refers to a community of microorganisms, including their genomes and interactions (see Chapter 25). The term human **microbiota** refers to the community of microorganisms that inhabit the human body. The human intestinal microbiota includes bacteria that receive shelter and nutrients in exchange for breaking down complex carbohydrates and producing vitamins. In addition, human intestinal microbiota ferment unused materials, prevent colonization by pathogenic bacteria, and strengthen the immune system. Recent research suggests that intestinal microbiota are involved in endocrine and neurological functions and may play a major role in diseases such as diabetes and obesity (see *Inquiring About: The Human Microbiota: Our Many Symbionts*).

Commensalism is taking without harming Commensalism is a type of symbiosis in which one species benefits and the other one is neither harmed nor helped. One example of commensalism is the relationship between social insects and scavengers, such as mites, beetles, or millipedes, which live in the social insects' nests. Certain types of silverfish, for example, move along in permanent association with marching columns of army ants and share the abundant food caught in the ant raids. The army ants derive no apparent benefit or harm from the silverfish.

Another example of commensalism is the relationship between a host tree and its epiphytes, which are smaller plants, such as orchids, ferns, or Spanish moss, attached to the host's branches (FIG. 54-13). The epiphyte anchors itself to the tree but does not obtain nutrients or water directly from it. Living on the tree enables it to obtain adequate light, water (as rainfall dripping down the branches), and required minerals (washed out of the tree's leaves by rainfall). Thus, the epiphyte benefits from the association, whereas the tree is apparently unaffected. (Epiphytes harm their host, however, if they are present in a large enough number to block sunlight from the host's leaves; in this instance, the relationship is no longer commensalism.)

Parasitism is taking at another's expense Parasitism is a symbiotic relationship in which one member, the **parasite**, benefits, whereas the other, the **host**, is adversely affected. The parasite obtains nourishment from its host. A parasite rarely kills its host directly but may weaken it, rendering it more vulnerable to predators, competitors, or abiotic stressors. When a parasite causes disease and sometimes the death of a host, it is called a **pathogen**.

Ticks and other parasites that live outside the host's body are called **ectoparasites**. Figure 32-9 shows a lamprey, an ectoparasite on fish. Parasites such as tapeworms that live within the host are called **endoparasites**. Parasitism is a successful lifestyle. By one estimate, more than two-thirds of all species are parasites, and nearly 1000 species of parasites (including fungi, bacteria, viruses, and other animals) live in or on the human species! Examples of human parasites include *Entamoeba histolytica*, an amoeba that causes amoebic

Pete Oxford/Getty Images

Figure 54-13 Commensalism

Spanish moss (*Tillandsia usneoides*) is a gray-colored epiphyte that hangs suspended from larger plants in the southeastern United States. Spanish moss is not a moss but a flowering plant in the bromeliad, or pineapple, family. It often grows 6 m (20 ft) or longer, but it is not a parasite and rarely harms the host tree. Spanish moss provides shelter to small animals such as bats, spiders, and snakes.

dysentery; *Plasmodium*, an apicomplexan that causes malaria; a variety of parasitic worms, such as blood flukes, tapeworms, pinworms, and hookworms (see Figs. 31-9 and 31-11); and *Pseudomonas aeruginosa*, an opportunistic bacterium responsible for many urinary tract and respiratory system infections.

Since the 1980s, wild and domestic honeybees in the United States have been dying off. According to the U.S. Department of Agriculture, many beekeepers have lost one-third to one-half of their bees each winter from a condition called colony collapse disorder. Habitat loss, severe weather, pesticide use, and higher pathogen load, as well as the mite *Varroa destructor* and smaller tracheal mites, have contributed to the problem. Although research continues, many scientists think that a combination of stressors may be the major reason for the continued honeybee decline (FIG. 54-14).

U.S. Department of Agriculture/Agricultural Research Service

Figure 54-14 Parasitism

Microscopic tracheal mites (*Acarapis woodi*) are endoparasites that live in the tracheal tubes of honeybees, clogging their airways so that they cannot breathe efficiently. Tracheal mites also suck the bees' circulatory fluid, weakening and eventually killing them. Entomologists think that the larger varroa mites (*not shown*), which are ectoparasites that also feed on the circulatory fluid, are more devastating to honeybee populations than are tracheal mites. Mites may also transmit viruses to their honeybee hosts.

CHECKPOINT 54.1

- **CONNECT** How are acorns, gypsy moths, and Lyme disease related?
- Why is an organism's realized niche usually narrower, or more restricted, than its fundamental niche?
- **CONNECT** Which principle of community ecology is illustrated by the following example: Two closely related species of small fish occupy the upper two feet of water when they occur in separate ponds, but if they are in the same pond, species *a* is more often found in the uppermost foot, and species *b* in the foot below.
- Name the three kinds of symbiosis and give an example of each.

54.2 Strength and Direction of Community Interactions

LEARNING OBJECTIVES

- 6 Distinguish between keystone species and dominant species.
- 7 Distinguish between bottom-up and top-down processes in ecosystem regulation.

There is a great deal of variation in the strength and direction of interactions among species within ecological communities. Some species, known as *keystone species*, are present in a community in low abundance and/or biomass but have

strong effects on their communities. Other species, known as *dominant species*, exert strong effects on their communities because they are present in great abundance and/or biomass.

Two types of control affect ecological communities, bottom-up processes and top-down processes. In *bottom-up processes* nutrient availability or food organisms whose population is directly affected by nutrient availability affect the abundance of other community organisms. In *top-down processes* predators impact the abundance of other populations in the community. We now examine these aspects of interactions among species within ecological communities.

Other species of a community depend on or are greatly affected by keystone species

Certain species, called **keystone species**, are crucial in determining the nature of the entire community—its species composition and ecosystem functioning. Keystone species are usually not the most abundant species in the community. Although present in relatively small numbers, the individuals of a keystone species profoundly influence the entire community because they often impact the amount of available food, water, or some other resource. Thus, the impact of keystone species is greatly disproportionate to their abundance. Identifying and protecting keystone species are crucial goals of conservation biology (see Chapter 57). If a keystone species disappears from a community, many other species in that community may become more common or rarer, or may even disappear.

The term *keystone species* was coined by ecologist Robert T. Paine in 1969, based on his experimental studies along the Pacific coast in the state of Washington (**FIG. 54-15**). Paine removed a predatory sea star, *Pisaster ochraceus*, from a rocky intertidal community that included barnacles, mussels, limpets, and chitons, all of which the sea star preyed on. He observed the changes in community structure that resulted and compared these changes to a nearby control area in which the sea stars were left intact. After the sea stars were removed, about half of the 15 species disappeared from the test area. They were crowded out by certain mussel and barnacle populations, which increased rapidly when freed from predation by the sea stars. Paine noted that when a keystone predator such as the sea star is removed from a community, the species diversity, abundance, and distribution of that community changes dramatically.

One problem with the concept of keystone species is that it is often difficult to measure all the direct and indirect effects of a keystone species on an ecosystem. Consequently, most evidence for the existence of keystone species is based on indirect observations rather than on experimental manipulations. For example, consider the fig tree. Because fig trees produce a continuous crop of fruits, they may be keystone species in tropical rain forests of Central America and South America. Fruit-eating monkeys, birds, bats, and other fruit-eating vertebrates of the forest do not normally consume large quantities of figs in their diets.

During that time of the year when other fruits are less plentiful, however, fig trees become important in sustaining fruit-eating vertebrates. It is therefore assumed that should the fig trees disappear, most of the fruit-eating vertebrates would

Figure 54-15 Rocky intertidal community at low tide

Pisaster sea stars and chitons cling to the rock during low tide. *Pisaster* sea stars range in color from purple to brown to orange. Photographed in the summer in the Pacific Northwest.

also disappear. In turn, should the fruit eaters disappear, the spatial distribution of other fruit-bearing plants would become more limited because the fruit eaters help disperse their seeds. Thus, protecting fig trees in such tropical rainforest ecosystems probably increases the likelihood that monkeys, birds, bats, and many other tree species will survive. The question is whether this anecdotal evidence of fig trees as keystone species is strong enough for policy makers to grant special protection to fig trees.

Like the *Pisaster* sea stars, many keystone species are top predators; for example, consider the gray wolf. Where wolves were hunted to extinction, populations of elk, deer, and other larger herbivores increased exponentially. As these herbivores overgrazed the vegetation, many plant species that could not tolerate such grazing pressure disappeared. Smaller animals such as rodents, rabbits, and insects declined in number because the plants they depended on for food were now less abundant. The number of foxes, hawks, owls, and badgers that prey on these small animals decreased, as did the number of ravens, eagles, and other scavengers that eat wolf-kill. Thus, the disappearance of the wolf resulted in communities with considerably less biological diversity.

The reintroduction of wolves to Yellowstone National Park in 1995 has given ecologists a unique opportunity to study the impact of a keystone species. The wolf's return has already caused substantial changes for other residents in the park. The top predator's effects have ranged from altering relationships among predator and prey species to transforming vegetation profiles. Coyotes are potential prey for wolves, and wolf packs have decimated some coyote populations. A reduction in coyotes has allowed populations of the coyotes' prey, such as ground squirrels and chipmunks, to increase. Scavengers such

as ravens, bald eagles, and grizzly bears have benefited from dining on scraps from wolf-kills.

Biologists think prey populations of elk in Yellowstone may now be in balance with the wolf population. Researchers have also recorded increases in the numbers of bear and cougar, which also feed on elk, resulting in a more balanced, healthier ecosystem. Interestingly, researchers have reported increases in the beaver population, resulting from the reintroduction of the wolves, part of the continued cascade effect. Apparently, wolves keep elk herds on the move, which reduces browsing on willow stems. The recovery of willow stands supports more beavers and an expanded habitat for songbirds. The beavers continue the cascade effect in the ecosystem by building more dams. The ponds and streams become deeper, supporting an expanded fish population.

Dominant species influence a community as a result of their greater size or abundance

In contrast to keystone species, which have a large impact out of proportion to their abundance, **dominant species** greatly affect the community because they are very common. Trees, the dominant species of forests, change the local environment. Trees provide shade, which changes both the light and moisture availability on the forest floor. Trees provide numerous habitats and *microhabitats* (such as a hole in a tree trunk or a rotting log) for other species. Forest trees also provide food for many organisms and therefore play a large role in energy flow through the forest ecosystem. Similarly, cordgrass (*Spartina*) is the dominant species in salt marshes, prairie grass in grasslands, and kelp in kelp beds. Animals are also dominant species. Corals, for example, are dominant species in coral reefs, and cattle are dominant species in overgrazed rangelands. Typically, a community has one or a few dominant species, and most other species are relatively rare.

Ecosystem regulation occurs from the bottom up and top down

One question that ecologists have recently considered is which regulatory process—bottom-up or top-down—is more significant in the regulation of various ecosystems. Both energy flow (see Fig. 1-8) and cycles of matter are involved in bottom-up and top-down processes. **Bottom-up processes** are based on **food webs**, the interconnected series of organisms through

which energy flows in an ecosystem. Food webs always have plants or other producers at the first (lowest) trophic level (FIG. 54-16a). (A *trophic level* is an organism's position in a food web; e.g., producers are the first trophic level, and plant-eating herbivores are the second level.) In a sense, the biogeochemical cycles that regenerate necessary nutrients such as nitrates and phosphates for producers to assimilate are located “under” the first trophic level. Thus, bottom-up processes regulate ecosystem function by nutrient cycling and by availability of other resources. If bottom-up processes dominate an ecosystem, the availability of resources such as water or soil minerals controls the number of producers, which controls the number of herbivores, which controls the number of carnivores. (Recall the discussion earlier in this chapter explaining that *limiting resources* tend to restrict the ecological niches of organisms, which affects population size.)

Bottom-up processes apparently predominate in certain aquatic ecosystems in which nitrogen or phosphorus is limiting. An experiment in which phosphorus was added to a phosphorus-deficient river (the Kaparuk River in Alaska) resulted in an increase in algae, followed over time by increased populations of aquatic insects, other invertebrates, and fishes.

In contrast, **top-down processes** regulate ecosystem function by trophic interactions, particularly from the highest trophic level (FIG. 54-16b). Ecosystem regulation by top-down processes occurs because carnivores eat herbivores, which eat producers, which impacts levels of nutrients. If top-down processes dominate an ecosystem, the effects of an increase in the population of top predators cascades down the food web through the herbivores and producers. In fact, top-down processes are also known as a *trophic cascade*.

A change in the feeding preferences of orcas, off the coast of Alaska, provides an excellent example of a trophic cascade. A few decades ago, when orcas began preying on sea otters, the sea otter population sharply declined. As sea otters have declined, the number of sea urchins, which sea otters eat, has

increased. Sea urchins eat kelp, the producers at the base of the food web, and the increase in the number of sea urchins has caused a decline in kelp populations. Kelp forests help reduce levels of carbon dioxide, a greenhouse gas that contributes to climate warming (discussed in Chapter 57).

Top-down regulation appears to predominate in ecosystems with few trophic levels and low species richness. Such ecosystems may have only one or a few species of dominant herbivores, but those species have a strong impact on the producer populations. An excellent example of top-down regulation—reindeer introduced to the Pribilof Islands of Alaska overgrazed the vegetation until the plants were almost wiped out—was discussed in Chapter 53.

It may be that top-down and bottom-up regulatory processes are not mutually exclusive. In a 13-year study of a thorn-scrub community in north-central Chile, ecologists demonstrated that top-down regulation predominates in certain small desert mammals and plant species. However, during periodic El Niño events (discussed later in the chapter), the increase in precipitation resulted in bottom-up increases in producers and consumers. In this ecosystem, it appears that both top-down and bottom-up regulatory processes are important in trophic dynamics over an extended period.

CHECKPOINT 54.2

- Both dominant and keystone species exert strong effects on the character of a community, but in different ways. How do dominant species and keystone species differ?
- PREDICT** Biologists think that the reintroduction of wolves to Yellowstone National Park will ultimately result in a more varied and lush plant composition. How could that occur? Is it an example of a bottom-up or top-down process? Why?

Figure 54-16 Bottom-up and top-down processes

54.3 Community Biodiversity

LEARNING OBJECTIVES

- Summarize the main determinants of species richness in a community and relate species richness to community stability.
- State the results of the analysis of the distance effect in South Pacific bird species.

Species diversity, species richness, and species evenness vary greatly from one community to another and are influenced by many biotic and abiotic factors. **Species diversity** is a measure of both the number of species within a community (*species richness*) and the relative importance of each species, based on its abundance, productivity, or size.

Species richness, the number of species in a community, is determined by counting the species of interest. Tropical rain forests and coral reefs are examples of communities with extremely high species richness. In contrast, geographically isolated islands and mountaintops exhibit low species

richness. **Species evenness** tells us about the relative abundance of one species compared to other species (FIG. 54-17).

Ecologists have developed various mathematical expressions, such as the *Shannon index*, to represent species diversity quantitatively. These *diversity indices* enable ecologists to compare species diversity in different communities. Conservation biologists use diversity indices as part of a comprehensive approach to saving biodiversity.

Ecologists seek to explain why some communities have more species than others

What determines the number of species in a community? No single conclusive answer exists, but several explanations appear plausible. They include the structural complexity of habitats, geographic isolation, habitat stress, closeness to the margins of adjacent communities, dominance of one species over others, and geologic history. Although these and other environmental

(a) Low species evenness. In this community the abundance of broomsedge is high relative to the abundance of other wildflowers (burdock, yarrow, and oxeye daisy). Therefore, the community has low species evenness.

(b) High species evenness. In this community each species has the same abundance, and the community has high species evenness.

Figure 54-17 Species evenness

Shown are two hypothetical communities with different species evenness but the same species richness (i.e., each has four species of wildflowers).

A community in which the vegetation is structurally complex generally provides animals with more kinds of food and hiding places than a community with a lower structural complexity.

Figure 54-18 Effect of community complexity on species richness

Data were compiled in comparable chaparral habitats (shrubby and woody areas) in Chile, South Africa, and California. The structural complexity of vegetation (x-axis) is a numerically assigned gradient of habitats, based on height and density of vegetation, from low complexity (very dry scrub) to high complexity (woodland). After Cody, M.L., and J.M. Diamond, eds., *Ecology and Evolution of Communities* (Harvard University Press, Cambridge, MA, 1975).

PREDICT What would a species richness graph look like if the data were compiled from a tundra habitat?

factors have positive or negative effects on species richness, there are exceptions and variations in every explanation. Some explanations vary at different spatial scales: an explanation that seems to work at a large geographic scale (such as a continent) may not work at a smaller local scale (such as a meadow).

In many habitats, species richness is related to the structural complexity of habitats. In terrestrial environments, the types of plants growing in an area typically determine structural complexity. A structurally complex community, such as a forest, offers a greater variety of potential ecological niches than does a simple community, such as an arid desert or semi-arid grassland (FIG. 54-18). An already complex habitat, such as a coral reef, may become even more complex if species potentially capable of filling vacant ecological niches evolve or migrate into the community because these species create “opportunities” for additional species. Thus, it appears that species richness is self-perpetuating to some degree.

Species richness is inversely related to the geographic isolation of a community. Isolated island communities are generally much less diverse than are communities in similar environments

Key Experiment

Does the geographic isolation of a community affect its species richness?

HYPOTHESIS: Islands close to the mainland (or to a large island) have a higher species richness than the islands that are farther from the mainland.

EXPERIMENT: The number of bird species was cataloged on South Pacific islands that are various distances from New Guinea, a source of colonizing species for these smaller islands. Each point on the graph represents a different island.

RESULTS AND CONCLUSION: The percentage of South Pacific bird species found on each island in the South Pacific is related to its distance from New Guinea. (New Guinea has 100% of the bird species living in that region.) Thus, species richness declines as the distance from New Guinea increases.

SOURCE: After J.M. Diamond, "Biogeographic Kinetics: Estimation of Relaxation Times for Avifaunas of Southwest Pacific Islands," *Proceedings of the National Academy of Sciences*, Vol. 69 (1972).

Figure 54-19 The distance effect

PREDICT Approximately what percentage of species have colonized islands 2000 km from New Guinea? 6000 km from New Guinea? Based on your answers, explain the relationship between species richness and geographic isolation.

found on continents. This difference is due partly to the *distance effect*, the difficulty encountered by many species in reaching and successfully colonizing the island (FIG. 54-19). Also, sometimes species become locally extinct as a result of random events. In isolated habitats such as islands or mountaintops, locally extinct species are not readily replaced. Isolated areas are usually small and have fewer potential ecological niches.

Generally, species richness is inversely related to the environmental stress of a habitat. Only those species capable of tolerating

extreme conditions live in an environmentally stressed community. Thus, the species richness of a highly polluted stream is low compared with that of a nearby pristine stream. Similarly, the species richness of high-latitude (farther from the equator) communities exposed to harsh climates is lower than that of lower latitude (closer to the equator) communities with milder climates (FIG. 54-20). This observation, known as the *species richness–energy hypothesis*, suggests that different latitudes affect species richness because of variations in solar energy. Greater energy may permit more species to coexist in a given region. Although the equatorial countries of Colombia, Ecuador, and Peru occupy only 2% of Earth's land, they contain a remarkable 46,000 native plant species. The continental United States and Canada, with a significantly larger land area, host a total of 19,000 native plant species. Ecuador alone contains more than 1600 native species of birds, twice as many as the United States and Canada combined.

Species richness is usually greater at the margins of distinct communities than in their centers. The reason is that an **ecotone**, a transitional zone where two or more communities meet, contains all or most of the ecological niches of the adjacent communities as well as some that are unique to the ecotone (see Fig. 56-24). This change in species composition produced at ecotones is known as the **edge effect**.

Species richness is reduced when any one species enjoys a position of dominance within a community; a dominant species may appropriate a disproportionate share of available resources, thus crowding out, or outcompeting, other species. Ecologist James H. Brown of the University of New Mexico has addressed species composition and richness in experiments conducted since 1977 in the Chihuahuan Desert of southeastern Arizona. In one experiment the removal of three dominant species, all kangaroo rats, from several plots resulted in an increased diversity of other rodent species. This increase was ascribed both to lowered competition for food and to an altered habitat because the abundance of grass species increased dramatically after the removal of the kangaroo rats.

Species richness is greatly affected by geologic history. Many scientists think that tropical rain forests are old, stable communities that have undergone relatively few widespread disturbances through Earth's history. (In the ecology field, a **disturbance** is any event in time that disrupts community or population structure.) During this time, myriad species evolved in tropical rain forests. In contrast, glaciers have repeatedly altered temperate and arctic regions during Earth's history. An area recently vacated by glaciers will have low species richness because few species have had a chance to enter it and become established. The idea that older, more stable habitats have greater species richness than habitats subjected to frequent, widespread disturbances is known as the *time hypothesis*.

Species richness may promote community stability

Traditionally, most ecologists assumed that community stability—the ability of a community to withstand disturbances—is a consequence of community complexity. That is, ecologists hypothesized that a community with considerable species

Key Point

Species richness increases along a polar → equatorial gradient. This correlation has been observed for many organisms, from plants to primates, in both terrestrial and marine environments.

Figure 54-20 Effect of latitude on species richness of breeding birds in North America

The species richness for three north-south transects (A, B, and C) are shown. Note that the overall number of breeding bird species is greater at lower latitudes toward the equator than at higher latitudes. However, this pattern is strongly modified by other factors, such as precipitation and surface features (e.g., mountains). After R.E. Cook, "Variation in Species Density of North American Birds," *Systematic Zoology*, Vol. 18 (1969).

PREDICT How might an increase in temperature over time (climate change) affect species richness in Alaska?

richness is more stable than a community with less species richness. According to this view, the greater the species richness, the less critically important any single species should be. With many possible interactions within the community, it appears unlikely that any single disturbance could affect enough components of the system to make a significant difference in its functioning.

Supporting evidence for this hypothesis is found in destructive outbreaks of pests being more common in cultivated fields, which have a low species richness, than in natural communities with a greater species richness. As another example, the almost complete loss of the American chestnut tree to the chestnut blight fungus had little ecological effect on the moderately diverse Appalachian woodlands of which it was formerly a part.

Ongoing studies by David Tilman of the University of Minnesota and John Downing of the University of Iowa have strengthened the link between species richness and community stability. In their initial study, they established and monitored 207 plots of various grassland species in Minnesota for seven years. During the study period, Minnesota's worst drought in 50 years occurred (1987–1988). The ecologists found that those plots with the greatest number of plant species lost less ground cover, as measured by dry weight, and recovered faster than species-poor plots. Later studies by Tilman and his colleagues supported these conclusions and showed a similar effect of species richness on community stability during non-drought years. Similar work by almost three dozen ecologists at eight grassland sites in Europe also supports the link between species richness and community stability.

Some scientists do not agree with the conclusions of Tilman and other research groups that the presence of more species confers greater community stability. These critics argue that it is difficult to separate species number from other factors that could affect productivity. They suggest that it would be better to start with established ecosystems and study what happens to their productivity when plants are removed.

Another observation that adds a layer of complexity to the species richness–community stability debate is that populations of individual species within a species-rich community often vary significantly from year to year. It may seem paradoxical that variation within populations of individual species relates to the stability of the entire community. When you consider all the interactions among the organisms in a community, however, it is obvious that some species benefit at the expense of others. If one species declines during a particular year, other species that compete with it may flourish. Thus, if an ecosystem contains more species, it is likely that at least some will be resistant to any given disturbance.

✓ CHECKPOINT 54.3

- **CONNECT** How is the species richness of a community related to geographic isolation?
- **CONNECT** How is the structural complexity of habitats relevant to species richness?
- **CONNECT** How is the species richness of a community related to the environmental stress of a habitat?

54.4 Community Development

🎯 LEARNING OBJECTIVES

- 10 Define *succession* and distinguish between primary and secondary succession.
- 11 Describe the intermediate disturbance hypothesis.
- 12 Discuss the two traditional views of the nature of communities: Clements's organismic model and Gleason's individualistic model.

A community does not spring into existence full-blown; rather, it develops gradually through a series of stages, each dominated by different organisms. The process of community development over time, which involves species in one stage being replaced by different species, is called **succession**. An area is initially colonized by certain early successional species that give way over time to others, and then, in turn, give way much later to late-successional species.

Succession is usually described in terms of the changes in the species composition of an area's vegetation, although each successional stage also has its own characteristic kinds of animals and other species. The time involved in succession is on the order of tens, hundreds, or thousands of years, not the millions of years involved in the evolutionary time scale.

Ecologists distinguish between two types of succession: primary and secondary. **Primary succession** is the change in species composition over time in a habitat that was not previously inhabited by organisms. No soil exists when primary succession begins. Bare rock surfaces, such as recently formed volcanic lava and rock scraped clean by glaciers, are examples of sites where primary succession might take place (FIG. 54-21).

Sierralarra/PhotoM/Getty Images

(a) After the glacier's retreat, lichens initially colonize the gravel moraine. Mosses and shallow rooted herbs such as mountain avens (*Dryas*) follow.

Don Paulson/Alamy Stock Photo

(b) Dense mats of low-growing *Dryas* plants dominate the landscape, stabilizing the thin layer of developing soil.

Don Paulson/Alamy Stock Photo

(d) As the condition of the soil improves, Sitka spruce (*Picea sitchensis*) replaces the alder community. After several hundred years, the forest consists of Sitka spruce and western hemlock (*Tsuga heterophylla*).

Jupiter Images

(c) Alders replace the *Dryas* community. Both alders (*Alnus*) and *Dryas* have nitrogen-fixing bacteria in root nodules that improve the nitrogen content of the soil.

Figure 54-21
Primary succession following retreating glaciers

Ecologists have documented primary succession as glaciers have retreated at Glacier Bay National Park, Alaska.

The Indonesian island of Krakatoa has provided scientists with a perfect long-term study of primary succession in a tropical rain forest. In 1883, a volcanic eruption destroyed virtually all life on the island. Ecologists have surveyed the ecosystem during the years since the devastation to document the return of life-forms. In the 1990s, ecologists found that the progress of primary succession was extremely slow, in part because of Krakatoa's isolation (recall the distance effect discussed earlier in the chapter). Many species are limited in their ability to disperse over water. Krakatoa's forest, for example, may have only one-tenth the tree species richness of undisturbed tropical rain forest of nearby islands. The lack of plant diversity has, in turn, limited the number of colonizing animal species. In a forested area of Krakatoa where zoologists would expect more than 100 butterfly species, for example, there are only 2.

Secondary succession is the change in species composition that takes place after some disturbance removes the existing vegetation; soil is already present at these sites. Abandoned agricultural fields or open areas produced by forest fires are common examples of sites where secondary succession occurs. During the summer of 1988, wildfires burned approximately one-third of Yellowstone National Park. This natural disaster provided a valuable chance for ecologists to study secondary succession in areas that had been forests. After the conflagration, gray ash covered the forest floor, and most of the trees, although standing, were charred and dead. Secondary succession in Yellowstone has occurred rapidly since 1988. Less than a year later, in the spring of 1989, trout lily and other herbs sprouted and covered much of the ground. By 1998, a young forest of knee-high to shoulder-high lodgepole pines dominated the area. Douglas fir seedlings also began appearing in 1998. Ecologists continue to monitor the changes in Yellowstone as secondary succession unfolds.

Disturbance influences succession and species richness

Early studies suggested that succession inevitably progressed to a stable and persistent community, known as a *climax community*, which was determined solely by climate. Periodic disturbances, such as fires or floods, were not thought to exert much influence on climax communities. If the climax community were disturbed in any way, it would return to a self-sustaining, stable equilibrium in time.

This traditional view of stability has fallen out of favor. The apparent end-point stability of species composition in a "climax" forest is probably the result of how long trees live relative to the human lifespan. It is now recognized that forest communities never reach a state of permanent equilibrium but instead exist in a state of continual disturbance. The species composition and relative abundance of each species vary in a mature community over a range of environmental gradients, although the community retains a relatively uniform appearance overall.

Because all communities are exposed to periodic disturbances, both natural and human-induced, ecologists have long tried to understand the effects of disturbance on species richness. A significant advance was the development of the

intermediate disturbance hypothesis by Joseph H. Connell. When he examined species richness in tropical rain forests and coral reefs, he proposed that species richness is greatest at moderate levels of disturbance (FIG. 54-22). At a moderate level of disturbance, the community is a mosaic of habitat patches at different stages of succession; a range of sites exists, from those that were recently disturbed to those that have not been disturbed for many years. When disturbances are frequent or intense, only those species best adapted to earlier stages of succession persist, whereas low levels of disturbance allow late-successional species to dominate to such a degree that other species disappear. For example, when periodic wildfires are suppressed in forests, reducing disturbance to a low level, some of the "typical" forest herbs decline in number or even disappear.

One of the difficulties with the intermediate disturbance hypothesis is defining precisely what constitutes an "intermediate" level of disturbance. Despite this problem, the intermediate disturbance hypothesis has important ramifications for conservation biology because it tells us that we cannot maintain a particular community simply by creating a reserve around it. Both natural and human-induced disturbances will cause changes in species composition, and humans may have to intentionally intervene to maintain the species richness of the original community. What kind of and how much human intervention is necessary to maintain species richness is controversial (we discuss this issue in Chapter 57).

Ecologists continue to study community structure

One of the major issues in community ecology, from the early 1900s to the present, is the nature of communities. Are communities highly organized systems of predictable species, or are they abstractions produced by the minds of ecologists?

U.S. botanist Frederick E. Clements (1874–1945) was struck by the worldwide uniformity of large tracts of vegetation, such as tropical rain forests in South America, Africa, and Southeast Asia. He also noted that even though the species composition of a community in a particular habitat may be

Figure 54-22 Intermediate disturbance hypothesis

Species richness is greatest at an intermediate level of disturbance. After J.H. Connell, "Diversity in Tropical Rain Forests and Coral Reefs," *Science*, Vol. 199 (1978).

Key Point

Most communities are individualistic associations of species rather than distinct units that act like “superorganisms.”

(a) **Organismic model.** According to this hypothesis, communities are organized as distinct units. Each of the four communities shown (numbered brackets) consists of an assemblage of distinct species (each colored curve represents a single species). The arrows indicate ecotones, regions of transition along community boundaries.

(b) **Individualistic model.** This model predicts a more random assemblage of species along a gradient of environmental conditions.

(c) **Tree species in Wisconsin forests, which are distributed along a moisture gradient, more closely resemble the individualistic model.** The “importance value” (y-axis) of each species in a given location combines three aspects (population density, frequency, and size).

Figure 54-23 Nature of communities

(c) Adapted from J.T. Curtis, *The Vegetation of Wisconsin* (University of Wisconsin Press, Madison, 1959).

VISUALIZE Create a graph with the same x-axis and y-axis titles as Figure 54-23c and show what the curves for a palm tree and a cactus might look like.

different from that of a community in a habitat with a similar climate elsewhere in the world, overall the components of the two communities are usually similar. He viewed communities as something like “superorganisms” whose member species cooperated with one another in a manner that resembled the cooperation of the parts of an individual organism’s body. Clements’s view was that a community went through certain stages of development, like the embryonic stages of an organism, and eventually reached an adult state; the developmental process was succession, and the adult state was the climax community. This cooperative view of the community, called the **organismic model**, stresses the interaction of the members, which tend to cluster in tightly knit groups within discrete community boundaries (FIG. 54-23a).

Opponents of the organismic model, particularly U.S. ecologist Henry A. Gleason (1882–1975), held that biological interactions are less important in the production of communities than are environmental gradients (such as climate and soil) or even chance. Indeed, the concept of a community is questionable. It may be a classification category with no reality, reflecting little more than the tendency of organisms with similar environmental requirements to live in similar places. This school of thought, called the **individualistic model**, emphasizes species individuality, with each species having its own particular abiotic living requirements. It holds that communities are therefore not interdependent associations of organisms. Rather, each species is independently distributed across a continuum of areas that meets its own individual requirements (FIG. 54-23b).

Debates such as this one over the nature of communities are an integral part of the scientific process because they fuel discussion and research that lead to a better understanding of broad scientific principles. Studies testing the organismic and individualistic hypotheses of communities do not support Clements’s interactive concept of communities as discrete units. Instead, most studies favor the individualistic model. As shown in FIGURE 54-23c, tree species in Wisconsin forests are distributed in a gradient from wet to dry environments. Also, studies of plant and animal movements during the past 14,000 years support the individualistic model because it appears that individual species, not entire communities, became redistributed in response to changes in climate.

CHECKPOINT 54.4

- How does primary succession differ from secondary succession?
- What is Connell’s intermediate disturbance hypothesis?
- How do the organismic and individualistic models of the nature of communities differ?

Summary: Focus on Learning Objectives

54.1 Community Structure and Functioning (page 1172)

1 Define **ecological niche** and distinguish between an organism's **fundamental niche** and its **realized niche**.

- The distinctive lifestyle and role of an organism in a community is its **ecological niche**. An organism's ecological niche takes into account all abiotic and biotic aspects of the organism's existence. An organism's **habitat** (where it lives) is one of the parameters used to describe the niche.
- Organisms potentially exploit more resources and play a broader role in the life of their community than they actually do. The potential ecological niche for an organism is its **fundamental niche**, whereas the niche it actually occupies is its **realized niche**.

2 Define **competition** and distinguish between **interspecific** and **intraspecific** competition.

- Competition** occurs when two or more individuals attempt to use the same essential resource, such as food, water, shelter, living space, or sunlight.
- Competition occurs among individuals within a population (**intraspecific competition**) or between different species (**interspecific competition**).

3 Summarize the concepts of the **competitive exclusion principle**, **resource partitioning**, and **character displacement**.

- According to the **competitive exclusion principle**, two species cannot occupy the same niche in the same community for an indefinite period; one species is excluded by another as a result of competition for a limiting resource.
- The evolution of differences in resource use, known as **resource partitioning**, reduces competition between similar species.
- Competition among some species is reduced by **character displacement**, in which their structural, ecological, and behavioral characteristics diverge where their ranges overlap.

4 Define **predation** and describe the effects of **natural selection** on **predator-prey** relationships.

- Predation** is the consumption of one species (the *prey*) by another (the *predator*). During **coevolution** between predator and prey, more efficient ways to catch prey evolve in the predator species, and better ways to escape the predator evolve in the prey species.

5 Distinguish among **mutualism**, **commensalism**, and **parasitism**, and give examples of each.

- Symbiosis** is any intimate or long-term association between two or more species. The three types of symbiosis are mutualism, commensalism, and parasitism.
- In **mutualism**, both partners benefit. Three examples of mutualism are *nitrogen-fixing bacteria* and legumes, *zooxanthellae* and corals, and *mycorrhizae* (fungi and plant roots).

- In **commensalism**, one organism benefits and the other is unaffected. Two examples of commensalism are silverfish and army ants, and epiphytes and larger plants.
- In **parasitism**, one organism (the **parasite**) benefits and the other (the **host**) is harmed. One example of parasitism is mites that grow in or on honeybees. Some parasites are **pathogens** that cause disease.

54.2 Strength and Direction of Community Interactions (page 1183)

6 Distinguish between **keystone species** and **dominant species**.

- Keystone species** are present in relatively small numbers but are crucial in determining the species composition and ecosystem functioning of the entire community.
- In contrast to keystone species, which have an effect that is out of proportion to their abundance, **dominant species** greatly affect the community of which they are a part because they are very common.

7 Distinguish between **bottom-up** and **top-down** processes in **ecosystem regulation**.

- If **bottom-up processes** dominate an ecosystem, the availability of resources such as minerals controls the number of producers (i.e., the lowest trophic level), which controls the number of herbivores, which controls the number of carnivores.
- Top-down processes** regulate ecosystems from the highest trophic level, by consumers eating producers. If top-down processes dominate an ecosystem, an increase in the number of top predators cascades down the food web through the herbivores and producers.

54.3 Community Biodiversity (page 1185)

8 Summarize the main determinants of **species richness** in a community and relate **species richness** to **community stability**.

- Community complexity is expressed in terms of **species richness**, the number of species within a community, and **species diversity**, a measure of the relative importance of each species within a community based on abundance, productivity, or size.
- Species richness is often great in a habitat that has structural complexity; in a community that is not isolated (the distance effect) or severely stressed; in a community where more energy is available (the species richness-energy hypothesis); in **ecotones** (transition zones between communities); and in communities with long histories without major **disturbances**, events that disrupt community or population structure.
- Several studies suggest that species richness may promote community stability.

9 State the results of the analysis of the **distance effect** in **South Pacific bird species**.

- The number of bird species found on each island in the South Pacific is inversely related to its geographic isolation, that is, to its distance from New Guinea. Species richness declines as the distance from New Guinea increases.

54.4 Community Development (page 1189)

10 Define *succession* and distinguish between primary and secondary succession.

- **Succession** is the orderly replacement of one community by another. **Primary succession** occurs in an area that has not previously been inhabited (such as bare rock). **Secondary succession** begins in an area where there was a pre-existing community and well-formed soil (such as abandoned farmland).

11 Describe the intermediate disturbance hypothesis.

- Disturbance affects succession and species richness. According to the **intermediate disturbance hypothesis**, species richness is greatest at moderate levels of disturbance, which create a mosaic of habitat patches at different stages of succession.

12 Discuss the two traditional views of the nature of communities: Clements's organismic model and Gleason's individualistic model.

- The **organismic model** views a community as a "super-organism" that goes through certain stages of development (succession) toward adulthood (climax). According to this view, biological interactions are primarily responsible for species composition, and organisms are highly interdependent.
- Most ecologists support the **individualistic model**, which challenges the concept of a highly interdependent community. According to this model, abiotic environmental factors are the primary determinants of species composition in a community, and organisms are somewhat independent of one another.

Test Your Understanding

Know and Comprehend

1. A symbiotic association in which organisms are beneficial to one another is known as (a) predation (b) interspecific competition (c) intraspecific competition (d) commensalism (e) mutualism
2. A species' _____ is the totality of its adaptations, its use of resources, and its lifestyle. (a) habitat (b) ecotone (c) ecological niche (d) competitive exclusion (e) coevolution
3. Primary succession occurs on (a) bare rock (b) newly cooled lava (c) abandoned farmland (d) a and b (e) a, b, and c
4. The tendency for two similar species to differ from each other more markedly in areas where they occur together is known as (a) Müllerian mimicry (b) Batesian mimicry (c) resource partitioning (d) competitive exclusion (e) character displacement
5. Competition with other species helps determine an organism's (a) ecotone (b) fundamental niche (c) realized niche (d) limiting resource (e) ecosystem
6. "Complete competitors cannot coexist" is a statement of the principle of (a) primary succession (b) limiting resources (c) Müllerian mimicry (d) competitive exclusion (e) character displacement
7. Most of the diverse populations of the human microbiota inhabit the (a) skin (b) intestine (c) mouth (d) body fluid (e) lungs
8. The _____ signifies that species richness is greater where two communities meet than at the center of either community. (a) edge effect (b) fundamental niche (c) character displacement (d) realized niche (e) limiting resource
9. An unpalatable species demonstrates its threat to potential predators by displaying (a) character displacement (b) limiting resources (c) cryptic coloration (d) aposematic coloration (e) competitive exclusion
10. A limiting resource does all the following *except* that it (a) tends to restrict the ecological niche of a species (b) is in short supply relative to a species' need for it (c) limits the presence of a species in a given community (d) results in an intermediate disturbance (e) may be limiting for only part of an organism's life cycle

Apply and Analyze

11. An ecologist studying several forest-dwelling, insect-eating bird species does not find any evidence of interspecific competition. The most likely explanation is (a) lack of a keystone species (b) low species richness (c) pronounced intraspecific competition (d) coevolution of predator-prey strategies (e) resource partitioning

12. Support for the individualistic model of community structure includes (a) the decline of honeybees because of two species of parasitic mites (b) the identification of fig trees as a keystone species in tropical forests (c) the competitive exclusion of one *Paramecium* species by another (d) the distribution of trees along a moisture gradient in Wisconsin forests (e) the effects of the removal of a dominant rodent species from an Arizona desert

Evaluate and Synthesize

13. In your opinion, are humans a dominant species or a keystone species? Explain your answer.
14. Many plants that produce nodules for nitrogen-fixing bacteria are common on disturbed sites. Explain how these plants might simultaneously compete with and facilitate other plant species.
15. **EVOLUTION LINK** The rough-skinned newt, which lives in western North America, stores a poison in its skin and is avoided by predators. However, several populations of garter snakes have undergone one or a few mutations that enable them to tolerate the toxin, and these snakes eat the newts with no ill effects. How has natural selection affected this predator-prey relationship? Based on what you have learned about evolutionary arms races, predict what may happen to the newts and the poison-resistant garter snakes over time.
16. **EVOLUTION LINK** Competition is an important part of Darwin's scientific theory of evolution by natural selection, and the evolution of features that reduce competition increases a population's overall fitness. Relate this idea to character displacement and resource partitioning in Darwin's finches.
17. **INTERPRET DATA** Examine the top and middle graphs in Figure 54-5. Are these examples of exponential or logistic population growth? Where is *K* in each graph? (You may need to refer to Chapter 53 to answer these questions.)
18. **SCIENCE, TECHNOLOGY, AND SOCIETY** Describe the ecological niche of humans. How have science and technology changed our realized niche during the past 1000 years?

55 Ecosystems and the Biosphere

KEY CONCEPTS

- 55.1** Studying the energy content of the different trophic levels provides insight into how energy flows through the biotic and abiotic components of ecosystems.
- 55.2** Carbon, nitrogen, water, and other materials cycle through both biotic and abiotic parts of ecosystems.
- 55.3** The abiotic environment—including solar radiation, the atmosphere, the ocean, climate, and fire—helps shape the biotic portion of ecosystems.
- 55.4** Ecosystem ecologists focus on chemical, physical, and biological processes of ecosystems to learn how ecosystems function.

PHOTO: Beaver dam. American beavers (*Castor canadensis*) built this dam out of sticks and mud. Their construction altered the water flow of the Snake River. Photographed on Snake River, Pacific Northwest.
CE Photography/Shutterstock.com

Planet Earth has often been compared to a vast spaceship, inhabited by diverse communities of organisms. As Earth orbits around the sun, these organisms use the sun's energy to produce oxygen, transfer energy, and recycle water and minerals (inorganic nutrients) with great efficiency. Yet none of these ecological processes would be possible without the abiotic (nonliving) environment of spaceship Earth. As the sun warms the planet, it powers the hydrologic cycle (causes precipitation), drives ocean currents and atmospheric circulation patterns, and produces much of the climate to which organisms have adapted. The sun also supplies the energy that almost all organisms use to carry on life processes.

Individual communities and their abiotic environments are **ecosystems**, which are the basic units of ecology. An ecosystem encompasses all the interactions among organisms living together in a particular place and among those organisms and their abiotic environment. **Ecosystem ecology** is a subfield of ecology that studies energy flow and the cycling of chemicals among the interacting biotic and abiotic parts of an ecosystem.

Ecosystem interactions are complex because each organism responds not only to other organisms but to conditions in the atmosphere, soil, and water. In turn, organisms exert an effect on the abiotic environment, as when a beaver dam creates a pond in a formerly forested area (see photograph). The pond is formed as the beaver builds an island lodge that will be safe from predators. However, the beaver dam also regulates the flow of water in the stream or river: it holds back water during rainy periods and releases a controlled amount of water throughout the year, even during periods of drought.

Like communities, ecosystems vary in size, lack precise boundaries, and are nested within larger ecosystems. Earth's largest

ecosystem is the biosphere, which consists of all Earth's communities and their interactions and connections with the planet's abiotic environment: its water, soil, rock, and atmosphere.

55.1 Energy Flow through Ecosystems

LEARNING OBJECTIVES

- 1 Summarize the concept of energy flow through a food web.
- 2 Explain typical pyramids of numbers, biomass, and energy.
- 3 Distinguish between gross primary productivity and net primary productivity.

The passage of energy in a one-way direction through an ecosystem is known as **energy flow**. Energy enters an ecosystem as radiant energy (sunlight), a tiny portion (less than 1%) of which *producers* trap and use during photosynthesis. The energy, now in chemical form, is stored in the bonds of organic (carbon-containing) molecules such as glucose. When cellular respiration breaks these molecules apart, energy becomes available (in the form of ATP) to do work, such as repairing tissues, producing body heat, moving about, or reproducing. As the work is accomplished, energy escapes the organisms and dissipates into the environment as heat. Ultimately, this heat energy radiates into space. Thus, once an organism has used energy, the energy is unavailable for reuse (FIG. 55-1). (See also the discussion of the second law of thermodynamics in Chapter 7.)

In an ecosystem, energy flow occurs in **food chains**, in which energy from food passes from one organism to the next in a sequence. **Primary producers**, also called *autotrophs*, form the beginning of the food chain by capturing the sun's energy through photosynthesis. Producers, by incorporating the chemicals they manufacture into their own *biomass* (living material), become potential food resources for other organisms. Plants are the most significant producers on land, whereas algae and cyanobacteria are important producers in aquatic environments. (Alternative producers are photoheterotrophs and chemoautotrophs discussed in Chapters 9 and 25.) All other organisms in a community are **consumers**, also called *heterotrophs*, which extract energy from organic molecules produced by other organisms.

Food chains are divided into **trophic levels** (from the Greek *tropho*, which means "nourishment"). Producers occupy the first trophic level. **Herbivores**, which occupy the second trophic level, are *primary consumers* that eat plants. They obtain the chemical energy of the producers' molecules and the building materials used to construct their own tissues. Herbivores are, in turn, consumed by **carnivores**, *secondary consumers* that reap the energy stored in the herbivores' molecules. *Tertiary consumers* are carnivores that eat secondary consumers. **Omnivores** are consumers that eat a variety of organisms, both plant and animal. Omnivores and consumers occupy third or higher trophic levels depending on what they eat.

Some consumers, called **detritus feeders**, or **detritivores**, eat **detritus**, which is dead organic matter that includes animal carcasses, leaf litter, wood, and feces. Detritivores and microbial decomposers break down dead organisms and waste products.

Decomposers, also called **saprotrophs**, are a subset of detritus feeders. Decomposers include microbial heterotrophs

Key Point

Ecologists gain insights into how ecosystems function by examining energy flow and the energy content of each trophic level.

Key Point

Food webs in all but the simplest ecosystems are too complex to depict all their species and links in a simple diagram. Some links are stronger than others. As food webs change over time, new links are added, and some links are deleted.

Figure 55-2 A food web at the edge of an Eastern deciduous forest

This diagram illustrates only a few of the thousands of species and links that might be part of a food web at the edge of a deciduous forest.

PREDICT What could happen to this food web if drought conditions occurred?

and fungi. These organisms supply themselves with energy by externally breaking down organic molecules in remains (carcasses and body wastes) and ingesting the inorganic products. They typically release simple inorganic molecules, such as carbon dioxide and mineral salts, which may be reused by producers. Most bacteria and fungi are important decomposers of all

members of the food chain. (See Chapters 25 and 29.)

Simple food chains such as the one described rarely occur in nature because few organisms eat just one kind, or are eaten by just one other kind, of organism. More typically, the flow of energy and materials through ecosystems takes place in accordance with a range of food choices for each organism. In an ecosystem of average complexity, hundreds of alternative pathways are possible. Thus, a **food web**, which is a complex of interconnected food chains, is a more realistic model of the flow of energy and materials through ecosystems (**FIG. 55-2**).

Because food chains and food webs are descriptions of “who eats whom,” they indicate the negative effects predators have on their prey. For example, consider a simple food chain: grass → field mouse → owl. The owl, which kills and eats mice, obviously exerts a negative effect on the mouse population; in like manner, field mice, which eat grass seeds, reduce the grass population.

A trophic level in a food web also influences other trophic levels to which it is not directly linked. Producers and top carnivores do not usually exert direct effects on one another, yet each indirectly affects the other. In our example, the owls help the grasses by keeping the population of seed-eating mice under control. Likewise, the grasses benefit owls by supporting a population of mice on which the owl population feeds. These indirect interactions are the focus of current research and may be as important in food-web dynamics as direct predator–prey interactions.

The most important thing to remember about energy flow in ecosystems is that it is linear, or a one-way system. That is, energy moves along a food web from one trophic level to the next trophic level. Once an organism has used energy, however, it is lost as heat and is unavailable to any other organism in the ecosystem.

Ecological pyramids illustrate how ecosystems work

Ecologists sometimes compare trophic levels by determining the number of organisms, the biomass, or the relative energy found at each level. This information is presented graphically

as **ecological pyramids**. The base of each ecological pyramid represents the producers, the next level is the primary consumers (herbivores), the level above that is the secondary consumers (carnivores), and then tertiary consumers (carnivores), and so on. The relative area of each bar of the pyramid is proportional to what is being demonstrated.

A **pyramid of numbers** shows the number of organisms at each trophic level in a given ecosystem, with a larger area illustrating greater numbers for that section of the pyramid. In most pyramids of numbers, fewer organisms occupy each successive trophic level. Thus, in African grasslands the number of herbivores, such as zebras and wildebeests, is greater than the number of carnivores, such as lions. Inverted pyramids of numbers, in which higher trophic levels have more organisms than lower trophic levels, are often observed among decomposers, parasites, and herbivorous insects. One tree provides food for thousands of leaf-eating insects, for example. Pyramids of numbers are of limited usefulness because they do not indicate the biomass of the organisms at each level, nor do they indicate the amount of energy transferred from one level to another.

A **pyramid of biomass** illustrates the total biomass at each successive trophic level. **Biomass** is a quantitative estimate of the total mass, or amount, of living material; it indicates the amount of fixed energy at a particular time. Biomass units of measure vary: biomass may be represented as total volume, dry weight, or live weight. Typically, these pyramids illustrate a progressive reduction of biomass in succeeding trophic levels (**FIG. 55-3a**). Assuming an average biomass reduction of about 90% for each trophic level, 10,000 kg of grass should support 1000 kg of grasshoppers, which in turn support 100 kg of frogs. (The 90% reduction in biomass is an approximation; actual biomass reduction from one trophic level to the next varies widely.) If we use this logic, the biomass of frog eaters (such as snakes) could weigh, at most, only about 10 kg. From this brief exercise, you see that although carnivores do not eat producers, a large producer biomass is required to support carnivores in a food web.

Occasionally, we find an inverted pyramid of biomass in which the primary consumers outweigh the producers (**FIG. 55-3b**). In these instances, herbivores such as fishes and zooplankton (protozoa, tiny crustaceans, and immature stages

of many aquatic animals) consume large numbers of producers, which are usually unicellular algae that are short-lived and reproduce quickly. Thus, although at any point in time relatively few algae are present, the rate of biomass production of the primary consumers is much less than that of the producers.

A **pyramid of energy** indicates the energy content, often expressed as kilocalories (or kilojoules), per square meter per year of the biomass of each trophic level. A common method ecologists use to measure energy content is to burn a sample of tissue in a calorimeter; the heat released during combustion is measured to determine the energy content of the organic material in the sample. Energy pyramids always have large bases and get progressively smaller through succeeding trophic levels. This illustrates the fact that most energy dissipates into the environment, and only about 10% of the usable energy is passed on when there is a transition from one trophic level to the next. Less energy reaches each successive trophic level from the level beneath it because those organisms at the lower level use some of the energy to perform work, and some of it is lost as heat (**FIG. 55-4**). (Remember that no biological process is 100% efficient.) The second law of thermodynamics explains why there are few trophic levels: energy pyramids are short because of the dramatic reduction in energy content that occurs at each successive trophic level.

Ecosystems vary in productivity

The **gross primary productivity (GPP)** of an ecosystem is the rate at which energy is captured during photosynthesis.¹ Thus, GPP is the total amount of photosynthetic energy captured in a given period. Of course, plants and other producers must respire to provide energy for their life processes, and cellular respiration acts as a drain on photosynthetic output. Energy that remains in plant tissues after cellular respiration has occurred is called **net primary productivity (NPP)**. That is, NPP is the amount of biomass (the energy stored in plant tissues) found in excess of that broken down by a plant's cellular respiration for normal daily activities. NPP represents the rate

¹ Gross and net primary productivities are referred to as primary because plants and other producers occupy the first position in food webs.

(a) A pyramid of biomass for a tropical forest in Panama.

(b) An inverted biomass pyramid, such as that for plankton in the English Channel, occurs when a highly productive lower trophic level experiences high rates of turnover. Plankton are free-floating, mainly microscopic algae and animals.

Figure 55-3 Pyramids of biomass

These pyramids are based on the biomass at each trophic level and generally have a pyramid shape with a large base and progressively smaller areas for each succeeding trophic level. Biomass values are in grams of dry weight per square meter.

(a, b) Adapted from E.P. Odum, *Fundamentals of Ecology*, 3rd ed. (W.B. Saunders Company, Philadelphia, 1971), and based on studies by F.B. Golley and G.I. Child (a) and H.W. Harvey (b).

Figure 55-4 Pyramid of energy

A pyramid of energy for Silver Springs, Florida, represents energy flow, the functional basis of ecosystem structure. Energy values are in kilocalories per square meter per year. Note the substantial loss of usable energy from one trophic level to the next. The Silver Springs ecosystem is complex, but tape grass (producers), spiral-shelled snails (primary consumers), young river turtles (secondary consumers), gar (fish; tertiary consumers), and bacteria and fungi (saprotrophs) are representative organisms. When they are young, river turtles are carnivores and consume snails, aquatic insects, and worms; as adults, river turtles are herbivores. Based on H.T. Odum, "Trophic Structure and Productivity of Silver Springs, Florida," *Ecological Monographs*, Vol. 27 (1957).

at which this organic matter is actually incorporated into plant tissues to produce growth.

net primary productivity	=	gross primary productivity	−	plant respiration
(plant growth per unit area per unit time)		(total photosynthe- sis per unit area per unit time)		(per unit area per unit time)

Only the energy represented by net primary productivity is available for consumers, and of this energy only a portion is actually used by them. Both GPP and NPP are expressed as energy per unit area per unit time (e.g., kilojoules of energy fixed by photosynthesis per square meter per year) or as dry weight (e.g., grams of carbon incorporated into tissue per square meter per year).

Ecologists use different methods to measure net primary productivity, such as through calorimetry (previously described) and change in dry biomass per unit time. Scientists also determine NPP by measuring carbon dioxide uptake and oxygen uptake over time. Another method to assess NPP in plants is through recording the change in chlorophyll *a* concentration, which measures daily carbon dioxide fixation.

Herbivores and other consumers eventually consume all of a plant's net primary production. What happens to this energy? Consider the transfer of net primary production from a plant to a deer that eats the plant. Much of the energy stored in the plant material that the deer consumes—about 25%—is not digested and is lost in its feces. (This energy is not lost from the ecosystem because detritivores and decomposers will make use of it; it is lost from the deer's point of view, however.) Perhaps 55% of the energy that the deer takes in as food is released during cellular respiration and used to do work such as muscle contraction and to maintain and repair the deer's body. The remaining energy—less than 20%—is available to produce new biomass, that is, new tissues. This net energy available for biomass production by consumer organisms is called **secondary productivity**. An ecosystem's secondary productivity is based on its primary productivity.

Many factors may interact to determine primary productivity. Some plants are more efficient than others in fixing carbon. Environmental factors are also important. They include

the availability of solar energy, minerals, and water; other climate factors; the degree of maturity of the community; and the severity of human modification of the environment.

These factors are difficult to assess, particularly on a large scale. The summer of 2003, which was extremely hot and dry in Europe, provided ecologists with a chance to measure primary productivity changes in response to these unusual conditions. Based on their measurements, they estimate that GPP throughout Europe was reduced by 30% as a result of the heat and drought.

Ecosystems differ strikingly in their primary productivities (FIG. 55-5 and TABLE 55-1). On land, tropical rain forests have the highest productivity, probably as a result of the abundant rainfall, warm temperatures, and intense sunlight. As you might expect, tundra, because of its short, cool growing season, and deserts, because of their lack of precipitation, are the least productive terrestrial ecosystems. In ecosystems with comparable annual temperatures (e.g., temperate deciduous forest, temperate grassland, and temperate desert), water availability affects NPP. Availability of essential minerals such as nitrogen and phosphorus also affects NPP.

Wetlands (swamps and marshes) connect terrestrial and aquatic environments and are extremely productive. The most productive aquatic ecosystems are algal beds, coral reefs, and estuaries. The lack of available minerals in the sunlit region of the open ocean makes this area extremely unproductive, equivalent to an aquatic desert. Earth's major aquatic and terrestrial ecosystems are discussed in Chapter 56.

As primary productivity increases, species richness declines

Ecologists have observed that an ecosystem's species richness declines with increasing productivity. For example, the resource-poor depths of the Atlantic Ocean's abyssal plain have more species richness than productive shallow waters near the coasts. Ecologists are designing experiments to help explain the pattern, which has been documented with rodents in Israel, birds in South America, and large mammals in Africa. Mathematical ecosystem models suggest that a less productive environment has a *patchy distribution of resources* that reduces competition and allows a greater variety of organisms to coexist.

The bad news for global biodiversity is that humans are constantly enriching the environment, such as with nitrogen

Figure 55-5 View of Earth's net primary productivity

The colors on this NASA satellite image indicate how quickly plants took carbon in for every square meter of land during November, 2016. Values range from -1.0 gram of carbon per square meter per day (*tan*) to 6.5 grams per square meter per day (*dark green*). A negative value indicates that decomposition or respiration was greater than carbon production; more carbon was released to the atmosphere than plants captured. The least productive areas are deserts. The most productive regions are tropical rain forests. Images like this allow scientists to assess changes in productivity over time.

and phosphorus inputs from fossil fuels, fertilizers, and livestock. This continual enrichment is making Earth's ecosystems increasingly productive, but is costing the world a substantial reduction in species richness. Researchers in England conducted a long-term experiment in community composition by returning grasslands that had been heavily fertilized by conventional

Table 55-1 Net Primary Productivity (NPP) for Selected Ecosystems

Ecosystem	Average NPP (g dry matter/m ² /year)
Algal beds and reefs	2500
Tropical rain forest	2200
Swamp and marsh	2000
Estuaries	1500
Temperate evergreen forest	1300
Temperate deciduous forest	1200
Savanna	900
Boreal (northern) forest	800
Woodland and shrubland	700
Agricultural land	650
Temperate grassland	600
Upwelling zones in ocean	500
Lake and stream	250
Arctic and alpine tundra	140
Open ocean	125
Desert and semidesert scrub	90
Extreme desert (rock, sand, ice)	3

Adapted from R.H. Whittaker, *Communities and Ecosystems*, 2nd ed. (Macmillan New York, 1975).

agricultural practices to organic farming methods. Over a period of 15 years, species diversity increased by 300%, as native plants became reestablished, while the productivity decreased by about 50%. Although the tradeoff for greater species richness was reduced productivity, the researchers showed that a healthy balance between the two is possible to attain and maintain. (Other factors that affect species richness were discussed in Chapter 54.)

Humans consume an increasingly greater percentage of global primary productivity

Humans consume far more of Earth's resources than do any of the other millions of animal species. Peter Vitousek and co-workers at Stanford University calculated in 1986 how much of the global NPP is appropriated

for the human economy. When both direct and indirect human effects are accounted for, Vitousek estimated that humans use 32% to 40% of land-based annual NPP. Since 1986, scientists have done additional research on global ecology, resulting in improved data sets. In 2001, Stuart Rojstaczer and co-workers at Duke University used satellite-based data to determine a conservative estimate of land-based annual NPP appropriation by humans at 32%.

The take-home message from Vitousek's and Rojstaczer's research is simple. Essentially, human use of global productivity is competing with other species' needs for energy. Our use of so much of the world's productivity is contributing to the loss, through extinction or genetic impoverishment, of many species that have unique roles in maintaining functional ecosystems. Clearly, at these levels of consumption and exploitation of Earth's resources, human population growth threatens the planet's ability to support all its occupants.

Some toxins persist in the environment

You have seen how energy flows through food chains in ecosystems. Before leaving the discussion of food chains, let us consider how certain toxins, including some pesticides, radioactive isotopes, heavy metals such as mercury, and industrial chemicals such as polychlorinated biphenyls (PCBs), enter and pass through food chains. The effects of the pesticide DDT on some bird species first drew attention to the problem. Falcons, pelicans, bald eagles, and ospreys are generally secondary consumers that accumulate substances in their bodies from lower levels of the food chain. The birds are sensitive to traces of DDT, and DDT metabolites, in their tissues. A substantial body of scientific

Does DDT exhibit biological magnification as it moves through a food chain?

HYPOTHESIS: DDT, a persistent insecticide, increases in concentration at each level of a food chain.

EXPERIMENT: Biologists sampled the concentration of DDT in various organisms of a Long Island salt marsh.

TROPHIC LEVEL	AMOUNT OF DDT IN TISSUE
Tertiary consumer	Ring-billed gull (75.5 ppm)
Secondary consumer	Atlantic needlefish (2.07 ppm)
Secondary consumer	American eel (0.28 ppm)
Primary consumer	Shrimp (0.16 ppm)
Producers, primary consumers	Plankton (0.04 ppm)

RESULTS AND CONCLUSION: The level of DDT increased in the tissues of various organisms as DDT moved through the food chain from producers to consumers. Ring-billed gulls at the top of the food chain had approximately 1 million times as much DDT in their tissues as the concentration of DDT in the water (0.00005 ppm). (Plankton consisted of a mixture of phytoplankton and zooplankton.)

SOURCE: Based on data from G.M. Woodwell, C.F. Worster, Jr., and P.A. Isaacson, "DDT Residues in an East Coast Estuary: A Case of Biological Concentration of a Persistent Insecticide," *Science*, Vol. 156 (May 12, 1967).

Figure 55-6 Biological magnification of DDT (expressed as parts per million) in a Long Island salt marsh

PREDICT How might DDT be passed on by the ring-billed gull, and what might be the consequences?

evidence indicates that DDT accumulation causes birds to produce eggs that have extremely thin, fragile shells that usually break during incubation, causing the chicks' deaths. DDT also acts as an endocrine disruptor, reducing fertility due to the effects of males being feminized by the chemical. In 1962, U.S. biologist Rachel Carson published *Silent Spring*, which heightened public awareness about the dangers of DDT and other pesticides. After 1972, the year DDT was banned in the United States, the reproductive success of many birds gradually improved.

The effect of DDT on birds is the result of three characteristics of DDT (and other toxins that cause problems in food webs): its persistence, bioaccumulation, and biological magnification. Some toxins are extremely stable and may take many years to break down into less toxic forms. The **persistence** of synthetic pesticides and industrial chemicals is a result of their novel chemical structures. These toxins accumulate in the environment because ways to degrade them have not evolved in natural decomposers such as bacteria.

When an organism does not metabolize (break down) or excrete a persistent toxin, the toxin simply gets stored, usually in fatty tissues. Over time, the organism may accumulate high concentrations of the toxin. The buildup of such a toxin in an organism's body is known as **bioaccumulation**.

Organisms at higher trophic levels in food webs, such as tertiary consumers, tend to have greater concentrations of bio-accumulated toxins in their bodies than do those at

lower levels. The increase in concentration, which occurs as the toxin passes through successive levels of the food web, is known as **biological magnification**.

As an example of the concentrating characteristic of persistent toxins, consider a food chain studied in a Long Island salt marsh that was sprayed with DDT over a period of years for mosquito control (**FIG. 55-6**). Although this example involved a bird at the top of the food chain, it is important to recognize that *all* top carnivores, from fishes to humans, are at risk from biological magnification of persistent toxins. Because of this risk, currently approved pesticides have been tested to ensure that they do not persist and accumulate in the environment. Unfortunately, many countries in Africa, South America, and Asia still rely on DDT and other persistent toxins to control the spread of malaria and reduce crop loss. Continued DDT use is a global concern because the pesticide travels long distances in the upper atmosphere and has been deposited worldwide. DDT is present in Arctic and Antarctic animal populations and may be re-entering food chains in areas where glaciers are melting due to climate change.

The danger from DDT and other pesticides, however, does not end with the death of the terminal consumer. DDT and its metabolites remain in the environment and have a soil half-life of up to 30 years. Recall that many organisms reside in soil and sediment. In aquatic environments, the DDT half-life is 150 years.

CHECKPOINT 55.1

- **VISUALIZE** Draw a diagram tracing energy flow through a food web such as one found in a deciduous forest.
- **CONNECT** What are trophic levels, and how are they related to ecological pyramids?
- How do gross primary productivity (GPP) and net primary productivity (NPP) differ?

55.2 Cycles of Matter in Ecosystems

LEARNING OBJECTIVE

- 4 Describe the main steps in each of these biogeochemical cycles: the carbon, nitrogen, phosphorus, and hydrologic cycles.

Matter moves in numerous cycles from one part of an ecosystem to another; that is, it moves from one organism to another (in food chains) and from living organisms to the abiotic environment and back again. We call these cycles of matter **biogeochemical cycles** because they involve biological,

geologic, and chemical interactions. For all practical purposes, matter cannot escape from Earth's boundaries. The materials organisms use cannot be "lost," although this matter can end up in locations outside the reach of organisms for a long period. Usually, materials are reused and often recycled both within and among ecosystems.

We discuss four different biogeochemical cycles of matter—carbon, nitrogen, phosphorus, and water—as representative of all biogeochemical cycles. These four cycles are particularly important to organisms because they involve materials used to make the chemical components of cells.

Carbon dioxide is the pivotal molecule in the carbon cycle

Proteins, nucleic acids, lipids, carbohydrates, and other molecules essential to life contain carbon. Carbon is present in the atmosphere as the gas carbon dioxide (CO_2), which makes up 0.04% of the atmosphere. It is also present in the ocean and fresh water as dissolved carbon dioxide, that is, carbonate (CO_3^{2-}) and bicarbonate (HCO_3^-); other forms of dissolved inorganic carbon; and dissolved organic carbon from decay processes. Carbon is also present in rocks such as limestone (CaCO_3). The global movement of carbon between the abiotic environment, including the atmosphere and ocean, and organisms is known as the **carbon cycle** (FIG. 55-7).

Figure 55-7 A simplified diagram of the carbon cycle

All but a tiny fraction of Earth's estimated 10^{23} g of carbon is buried in sedimentary rocks and fossil fuel deposits. The values shown for some of the active pools in the global carbon budget are expressed as 10^{15} g of carbon. For example, the soil contains an estimated 1500×10^{15} g of carbon. Values from W.H. Schlesinger, *Biogeochemistry: An Analysis of Global Change*, 2nd ed. (Academic Press, San Diego, 1997), and several other sources.

During photosynthesis, plants, algae, and cyanobacteria remove carbon dioxide from the air and *fix*, or incorporate, it into organic compounds such as glucose. Plants use much of the glucose to make cellulose, starch, amino acids, nucleic acids, and other compounds.

Many of these compounds are used as fuel for cellular respiration by the producer that made them, by a consumer that eats the producer, or by a decomposer that breaks down the remains of the producer or consumer. The process of cellular respiration returns carbon dioxide to the atmosphere. A similar carbon cycle occurs in aquatic ecosystems between aquatic organisms and dissolved carbon dioxide in the water (not shown in Figure 55-7).

Some archaea fix carbon using atmospheric CO_2 . Other archaea, the methanogens, are decomposers and are the major source of methane in the atmosphere. The methanogens significantly contribute to global climate change (see discussion of methanogens in Chapter 25).

Sometimes the carbon in biological molecules is not recycled back to the abiotic environment for a long time and remains in reservoirs, or sinks, indefinitely. Carbon stored in the wood of trees may stay for several hundred years or even longer. Also, millions of years ago vast coal beds formed from the bodies of ancient trees that were buried and subjected to anaerobic conditions before they had fully decayed. Similarly, the oils of unicellular marine organisms probably gave rise to the underground deposits of oil and natural gas that accumulated in the geologic past. Coal, oil, and natural gas, called **fossil fuels** because they formed from the remains of ancient organisms, are vast deposits of carbon compounds, the end products of photosynthesis that occurred millions of years ago.

The process of burning, or combustion, may return the carbon in coal, oil, natural gas, and wood to the atmosphere. In combustion, organic molecules are rapidly oxidized (combined with oxygen) and converted to carbon dioxide and water with an accompanying release of light and heat.

An even greater amount of carbon that is stored for millions of years is incorporated into the shells of marine organisms. When these organisms die, their shells sink to the ocean floor, and sediments cover them, forming seabed deposits thousands of meters thick. The deposits are eventually cemented together to form limestone, a sedimentary rock. Earth's crust is dynamically active, and over millions of years, sedimentary rock on the bottom of the seafloor may lift to form land surfaces. When the process of geologic uplift exposes limestone, chemical and physical weathering processes slowly erode it away. This returns carbon to the water and atmosphere, where it is available to participate in the carbon cycle once again.

Human activities have disturbed the global carbon budget Before the Industrial Revolution, around 1750, the global carbon cycle was in a steady state. Enormous amounts of carbon moved to and from the atmosphere, ocean, and terrestrial ecosystems, but these movements within the global carbon cycle just about canceled out one another.

Since 1750, our industrial society has required a lot of energy, and we have burned increasing amounts of fossil fuels—coal, oil, and natural gas—to obtain this energy. This trend, along

with a greater combustion of wood as a fuel and the burning of large sections of tropical forest, has released CO_2 into the atmosphere at a rate greater than the natural carbon cycle can handle.

Earth's ocean absorbs much of this excess CO_2 from the atmosphere. In the ocean, some dissolved CO_2 is converted to carbonic acid (H_2CO_3), which is acidifying surface ocean waters. The pH of modern surface waters is about 0.1 pH unit lower than it was in preindustrial times, and models predict 1.4 pH units, or more, of further acidification during the next 300 years. *Ocean acidification* harms marine organisms, particularly those that produce skeletons and shells of calcium carbonate (CaCO_3), which dissolve in the presence of acid.

The level of atmospheric CO_2 has increased dramatically beginning in the last half of the 20th century (see Fig. 57-16). This rise in CO_2 was caused by human activities and is responsible for major changes in climate. Global climate change is causing a rise in sea level, changes in precipitation patterns, death of forests, extinction of organisms, and problems for agriculture. It will drive the displacement of thousands or even millions of people, particularly from coastal areas. (Chapter 57 contains a more thorough discussion of increasing atmospheric CO_2 and the potential effects of global climate change.)

Bacteria and archaea are essential to the nitrogen cycle

Nitrogen is crucial for all organisms because it is an essential part of proteins, nucleic acids, and chlorophyll. Because Earth's atmosphere is about 78% nitrogen gas (N_2), it would appear that there could be no possible shortage of nitrogen for organisms. However, molecular nitrogen is so stable that it does not readily combine with other elements. Therefore, the N_2 molecule must be broken apart before the nitrogen atoms combine with other elements to form proteins, nucleic acids, and chlorophyll. Chemical reactions that break up N_2 and combine nitrogen with other elements require a great deal of energy.

The **nitrogen cycle**, in which nitrogen cycles between the abiotic environment and organisms, has five steps: nitrogen fixation, nitrification, assimilation, ammonification, and denitrification (FIG. 55-8). Certain bacteria and archaea are exclusively involved in all these steps except assimilation.

The first step in the nitrogen cycle, biological **nitrogen fixation**, involves conversion of gaseous nitrogen (N_2) to ammonia (NH_3). This process fixes nitrogen into a form that organisms can use. Combustion, volcanic action, lightning discharges, and industrial processes also fix nitrogen as nitrate (NO_3^-). Certain archaea and nitrogen-fixing bacteria, including cyanobacteria and certain other free-living and symbiotic bacteria, carry on biological nitrogen fixation in soil and aquatic environments. These nitrogen-fixing prokaryotes employ an enzyme called **nitrogenase** to break up molecular nitrogen and combine the resulting nitrogen atoms with hydrogen.

Because nitrogenase functions only in the absence of oxygen, the prokaryotes that fix nitrogen insulate the enzyme from oxygen in some way. Some nitrogen-fixing prokaryotes live beneath layers of oxygen-excluding slime

Figure 55-8 A simplified diagram of the nitrogen cycle

The largest pool of nitrogen, estimated at 3.9×10^{21} g, is in the atmosphere. The values shown for selected nitrogen fluxes in the global nitrogen budget are expressed as 10^{12} g of nitrogen per year and represent terrestrial values. For example, each year humans fix an estimated 100×10^{12} g of nitrogen. Values from W.H. Schlesinger, *Biogeochemistry: An Analysis of Global Change*, 2nd ed. (Academic Press, San Diego, 1997), and several other sources.

on the roots of several plant species. Other important nitrogen-fixing bacteria, in the genus *Rhizobium*, live in oxygen-excluding swellings, or **nodules**, on the roots of legumes such as beans and peas and some woody plants (FIG. 55-9; also see Table 25-3).

In aquatic environments, bacteria and archaea perform most nitrogen fixation. Filamentous cyanobacteria have special oxygen-excluding cells called **heterocysts** that function to

Figure 55-9 Root nodules and nitrogen fixation

Root nodules on the roots of a pea plant provide an oxygen-free environment for nitrogen-fixing *Rhizobium* bacteria that live in them.

fix nitrogen (see Table 25-3). Some water ferns have cavities in which cyanobacteria live, in a manner comparable to the way *Rhizobium* lives in root nodules of legumes. Other cyanobacteria fix nitrogen in symbiotic association with cycads and other terrestrial plants or as the photosynthetic partner of certain lichens.

The second step of the nitrogen cycle is **nitrification** (see Fig. 55-8), the conversion of ammonia (NH_3) or ammonium (NH_4^+), formed when water reacts with ammonia, to nitrate (NO_3^-). Soil bacteria are responsible for the two-phase process of nitrification, which furnishes these bacteria, called *nitrifying bacteria*, with energy.

In the third step, **assimilation**, roots absorb ammonia (NH_3), ammonium (NH_4^+), or nitrate (NO_3^-) formed by nitrogen fixation and nitrification, and incorporate the nitrogen into proteins, nucleic acids, and chlorophyll. When animals consume plant tissues, they assimilate nitrogen by taking in plant nitrogen compounds and converting them to animal nitrogen compounds.

The fourth step, **ammonification**, is the conversion of organic nitrogen compounds into ammonia (NH_3) and ammonium ions (NH_4^+). Ammonification begins when organisms produce nitrogen-containing wastes such as urea in urine and uric acid in the wastes of birds (see Fig. 48-1). As these substances, along with the nitrogen compounds in dead organisms, decompose, nitrogen is released into the abiotic environment as ammonia (NH_3). The bacteria that perform ammonification in both the soil and aquatic environments are called *ammonifying bacteria*.

Most available nitrogen in the soil derives from the recycling of organic nitrogen by ammonification.

The fifth step of the nitrogen cycle is **denitrification**, the reduction of nitrate (NO_3^-) to gaseous nitrogen (N_2). Denitrifying prokaryotes reverse the action of nitrogen-fixing and nitrifying prokaryotes by returning nitrogen to the atmosphere as nitrogen gas. Denitrifying prokaryotes are anaerobic and therefore live and grow best where there is little or no free oxygen. For example, they are found deep in the soil near the water table, an environment that is nearly oxygen-free.

Human activities have changed the global nitrogen budget Human activities have disturbed the balance of the global nitrogen cycle. During the 20th century, humans more than doubled the amount of fixed nitrogen (nitrogen that has been chemically combined with hydrogen, oxygen, or carbon) entering the global nitrogen cycle. The excess nitrogen is seriously altering many terrestrial and aquatic ecosystems.

Large quantities of nitrogen fertilizer, for commercial farming operations and for residential use, are produced from nitrogen gas for agriculture. The increasing use of fertilizer has resulted in higher crop yields, but there are negative environmental effects from human-produced nitrogen. Nitrogen fertilizer is extremely mobile and is easily transferred from the land to rivers to estuaries to the ocean. Thus, the overuse of commercial fertilizer on the land causes water-quality problems that may help explain long-term declines in many coastal fisheries. The amount of nitrate or ammonium in most aquatic ecosystems is in limited supply and limits the growth of algae. Rain washes fertilizer into rivers and lakes, where it stimulates the growth of algae, some of which are toxic. As these algae die, their decomposition by bacteria robs the water of dissolved oxygen, which in turn causes other aquatic organisms, including many fishes, to suffocate.

Nitrates from fertilizer also leach (dissolve and wash down) through the soil and contaminate groundwater. Many people who live in rural areas drink groundwater. Groundwater contaminated by nitrates is dangerous, particularly for infants and small children.

Another human activity that affects the nitrogen cycle is the combustion of fossil fuels. When fossil fuels are burned, the nitrogen locked in organic compounds in the fuel is chemically altered and transferred to the atmosphere. In addition, the high temperature of combustion converts some atmospheric nitrogen to **nitrogen oxides**. Automobile exhaust is one of the main sources of nitrogen oxides. Nitrogen oxides are a necessary ingredient in the production of **photochemical smog**, a mixture of several air pollutants that injure plant tissues, irritate eyes, and cause respiratory problems in humans.

Nitrogen oxides also react with water in the atmosphere to form nitric acid (HNO_3) and nitrous acid (HNO_2). When these and other acids leave the atmosphere as precipitation (rain, sleet, snow, or hail), they decrease the pH of surface waters (lakes and streams) and soils. **Acid precipitation** includes rain, snow, fog, or dust that is unusually acidic (pH below 5.6). Acid precipitation has been linked to declining animal populations in aquatic ecosystems. On land, acid precipitation alters soil chemistry: certain essential minerals,

such as calcium and potassium, wash out of the soil and are therefore unavailable for plants. Nitrous oxide (N_2O), one of the nitrogen oxides, retains heat in the atmosphere (like CO_2) and so promotes global climate change.

Nitrous oxide also contributes to the depletion of ozone in the stratosphere. (See Chapter 2 for a discussion of acids and pH, and Chapter 57 for a discussion of global climate change and stratospheric ozone depletion.)

The phosphorus cycle lacks a gaseous component

Phosphorus does not exist in a gaseous state and therefore does not enter the atmosphere. In the **phosphorus cycle**, phosphorus cycles from the land to sediments in the ocean and back to the land (FIG. 55-10).

As water runs over rocks containing phosphorus, it gradually erodes the surface and carries off inorganic phosphate (PO_4^{3-}). The erosion of phosphorus rocks releases phosphate into the soil, where it is taken up by roots in the form of inorganic phosphates. Once in cells, phosphates are incorporated into a variety of biological molecules, including nucleic acids, ATP, and the phospholipids that make up cell membranes. Animals obtain most of their required phosphorus from the food they eat, although in some places drinking water may contain a substantial amount of inorganic phosphate. Phosphate released by decomposers becomes part of the pool of inorganic phosphate in the soil that plants reuse. Thus, like carbon and nitrogen, phosphorus moves through the food web as one organism consumes another.

Phosphorus cycles through aquatic ecosystems in much the same way as through terrestrial ecosystems. Dissolved phosphate enters aquatic ecosystems through absorption by algae and aquatic plants, which zooplankton and larger organisms consume. In turn, a variety of fishes and mollusks eat the zooplankton. Ultimately, decomposers break down wastes and dead organisms to release inorganic phosphate into the water, making it available for use again by aquatic producers.

Phosphate can be lost for varying time periods from biological cycles. Streams and rivers carry some phosphate to the ocean, where it is deposited on the seafloor and remains for millions of years. The geologic process of uplift may someday expose these reservoirs of seafloor sediments as new land surfaces, from which phosphate will be once again eroded. Phosphate deposits are also mined for agricultural use in phosphate fertilizers.

Humans affect the natural cycling of phosphorus In natural terrestrial communities, very little phosphorus is lost from the cycle, but few communities today are in a natural state, that is, unaltered in some way by humans. Land-denuding practices, such as the clear-cutting of timber, and erosion of agricultural and residential lands accelerate phosphorus loss from the soil into waterways. Excess phosphorus enriches the water, causing algal blooms that rob the water of dissolved oxygen. For practical purposes, phosphorus that washes from the land into the ocean is permanently lost from the terrestrial phosphorus cycle (and from further human use) because it remains in the ocean for millions of years.

Figure 55-11 A simplified diagram of the hydrologic cycle

The global water budget values shown for pools are expressed as cubic kilometers; values for fluxes (movements associated with arrows) are in cubic kilometers per year. The *starred value* (71,000 km³/yr) is the sum of both transpiration and evaporation from soil, streams, rivers, and lakes. Values from W.H. Schlesinger, *Biogeochemistry: An Analysis of Global Change*, 2nd ed. (Academic Press, San Diego, 1997), and several other sources.

55.3 Abiotic Factors in Ecosystems

LEARNING OBJECTIVES

- 5 Summarize the effects of solar energy on Earth's temperatures.
- 6 Discuss the roles of solar energy and the Coriolis effect in the generation of global air and water flow patterns.
- 7 Give two causes of regional precipitation differences.
- 8 Discuss the effects of fire on certain ecosystems.

You have seen how ecosystems depend on the abiotic environment to supply energy and essential materials (in biogeochemical cycles). Other abiotic factors such as solar radiation, the atmosphere, the ocean, climate, and fire also affect ecosystems. For a given abiotic factor, each organism living in an ecosystem has an optimal range in which it survives and reproduces. Water and temperature are probably the two abiotic factors that most affect organisms in ecosystems.

The sun warms Earth

The sun makes life on Earth possible. Without the sun's energy, the temperature on planet Earth would approach absolute zero (0 K or -273°C), and all water would be frozen, even in the ocean. The sun powers the hydrologic cycle, carbon cycle, and

other biogeochemical cycles and is the primary determinant of climate. Photosynthetic organisms capture the sun's energy and use it to make organic compounds that almost all forms of life require. Most of our fuels, such as wood, oil, coal, and natural gas, represent solar energy captured by photosynthetic organisms. Without the sun, almost all life on Earth would cease (see *Inquiring About: Life without the Sun* for an interesting exception).

The sun's energy, which is the product of a massive nuclear fusion reaction, is emitted into space in the form of electromagnetic radiation, especially ultraviolet, visible, and infrared radiation. About one-billionth of the total energy that the sun releases strikes the atmosphere, and of this tiny trickle of energy, a minute part operates the biosphere. On average, clouds and surfaces—especially snow, ice, and the ocean—immediately reflect away 30% of the solar radiation that falls on Earth (FIG. 55-12). Earth's surface and atmosphere absorb the remaining 70%, which runs the water cycle, drives winds and ocean currents, powers photosynthesis, and warms the planet. Ultimately, the continual radiation of long-wave infrared (heat) energy returns all this energy to space. When heat gains do not exactly balance losses, Earth heats up or cools down.

Temperature changes with latitude The most significant local variations in Earth's temperature are produced because the sun's energy does not uniformly reach all places. Our planet's roughly spherical shape and the tilted angle of its axis produce significant variation in the exposure of the surface to sunlight. The

Inquiring About

Life without the Sun

Is the sun the energy source for all ecosystems? A notable exception was discovered in the late 1970s in a series of hydrothermal vents in the eastern Pacific where seawater apparently had penetrated and been heated by the radioactive rocks below. During its time within Earth, the water had become charged with inorganic mineral compounds, including hydrogen sulfide (H_2S).

No light is available for photosynthesis, but hydrothermal vents support a rich ecosystem that contrasts with the surrounding “desert” of the deep-ocean floor. Giant, blood-red tube worms almost 3 m (10 ft) in length cluster in great numbers around the vents (see figure). Other animals around the hydrothermal vents include unique species of clams, crabs, barnacles, and mussels.

Scientists initially wondered what energy source sustains the organisms in this dark environment. Most deep-sea communities depend on the organic matter that drifts down from the surface waters; in other words, they rely on energy ultimately derived from photosynthesis. Hydrothermal vent communities, however, are too densely clustered and too productive to be dependent on chance encounters with organic material from surface waters.

Instead, chemoautotrophic prokaryotes occupy the base of the food web in these aquatic oases. These prokaryotes have enzymes that catalyze the

oxidation of hydrogen sulfide, yielding water plus sulfur or sulfate. Such chemical reactions are exergonic and provide the energy required to fix CO_2 dissolved in the water into organic compounds. Many of the animals consume the prokaryotes directly by filter-feeding, but others, such as the

D. Foster, Science VU-SHO/Visuals Unlimited

giant tube worms, get their energy from prokaryotes that live in their tissues.

Scientists continue to discover hydrothermal vent communities as they explore and map the ocean bottom. Researchers generate numerous questions about hydrothermal vent communities. How do the organisms find and colonize vents, which are ephemeral and widely scattered on the ocean floor? How have the inhabitants of these communities adapted to survive the harsh living conditions, including high pressure, high temperatures, and toxic chemicals? As vent community research continues, scientists hope to discover answers to these questions and to identify organisms that potentially have medicinal or industrial value, untapped resources to aid humanity.

Hydrothermal vent ecosystem. Chemoautotrophic prokaryotes living in the tissues of these tube worms (*Riftia pachyptila*) extract energy from hydrogen sulfide to manufacture organic compounds. These worms lack digestive systems. They depend on the organic compounds the prokaryotes provide, along with materials filtered from the surrounding water. Also visible in the photograph are some filter-feeding clams (yellow) and a crab (white).

Figure 55-12 The fate of solar radiation that reaches Earth

Most of the energy released by the sun never reaches Earth. The solar energy that does reach Earth warms the planet's surface, drives the hydrologic and other biogeochemical cycles, produces the climate, and powers almost all life through the process of photosynthesis.

sun's rays strike almost vertically near the equator, concentrating the energy and producing warmer temperatures. Near the poles, the sun's rays strike more obliquely and, as a result, are spread over a larger surface area. Also, rays of light entering the atmosphere obliquely near the poles must pass through a deeper envelope of air than those entering near the equator. This angle causes more of the sun's energy to be scattered and reflected back into space, which further lowers temperatures near the poles. Thus, the solar energy that reaches polar regions is less concentrated and produces lower temperatures than elsewhere.

Temperature changes with each season Earth's inclination on its axis (23.5 degrees from a line drawn perpendicular to the orbital plane) primarily determines the seasons. During half of the year (March 21 to September 22), the Northern Hemisphere tilts toward the sun, concentrating the sunlight and making the days longer (FIG. 55-13). During the other half of the year (September 22 to March 21), the Northern Hemisphere

Figure 55-13 Seasonal changes in temperature

Earth's inclination on its axis remains the same as Earth travels around the sun. Thus, the sun's rays hit the Northern Hemisphere obliquely during winter months and more directly during summer months. In the Southern Hemisphere, the sun's rays are oblique during the winter, which corresponds to the Northern Hemisphere's summer. At the equator, the sun's rays are approximately vertical on March 21 and September 22.

tilts away from the sun, giving it a lower concentration of sunlight and shorter days. The orientation of the Southern Hemisphere is just the opposite at these times. Summer in the Northern Hemisphere corresponds to winter in the Southern Hemisphere.

The atmosphere contains several gases essential to organisms

The atmosphere is an invisible layer of gases that envelops Earth. Oxygen (21%) and nitrogen (78%) are the predominant gases in the atmosphere, accounting for about 99% of dry air; other gases, including argon, carbon dioxide, neon, and helium, make up the remaining 1%. In addition, water vapor and trace amounts of various air pollutants, such as methane, ozone, dust particles, pollen, microorganisms, and chlorofluorocarbons (CFCs), are present. Atmospheric oxygen is essential to plants, animals, and other organisms that respire aerobically; and plants and other photosynthetic organisms also require carbon dioxide.

The atmosphere performs several essential ecological functions. It protects Earth's surface from most of the sun's ultraviolet radiation and X-rays as well as from lethal amounts of cosmic rays from space. Without this atmospheric shielding, life as we know it would cease. Although the atmosphere protects Earth from high-energy radiation, visible light and some infrared radiation can penetrate it, and they warm the surface and the lower atmosphere. This interaction between the atmosphere and solar energy is responsible for weather and climate.

Organisms depend on the atmosphere. However, they also help maintain and, in certain instances, modify its composition. For example, atmospheric oxygen increased to its present level as a result of billions of years of photosynthesis. Today, an approximate balance between oxygen-producing photosynthesis and oxygen-using aerobic respiration helps maintain the level of atmospheric oxygen.

The sun drives the global atmospheric circulation

In large measure, differences in temperature that are due to variations in the amount of solar energy at different locations on Earth drive the circulation of the atmosphere. The warm surface near the equator heats the air with which it comes into contact, causing this air to expand and rise. As the warm air rises, it flows away from the equator, cools, and sinks again (FIG. 55-14). Much of it recirculates to the same areas it left, but the remainder splits and flows in two directions, toward the poles. The air chills enough to sink to the surface at about 30 degrees north and south latitudes. Similar upward movements of warm air and its subsequent flow toward the poles occur at higher latitudes, farther from the equator. At the poles, the cold polar air sinks and flows toward the lower

Figure 55-14 Atmospheric circulation

The greatest solar energy input occurs at the equator and heats air most strongly in that area. The air rises and travels poleward (*left*) but is cooled in the process, so much of it descends again around 30 degrees latitude in both hemispheres. At higher latitudes, the patterns of air movement are more complex.

The driving force of wind produces Earth's major surface ocean currents.

Figure 55-15 Major surface ocean currents
Each current has characteristic temperature and flow patterns.

PREDICT How could currents be affected by global climate change?

latitudes, generally beneath the warm air that simultaneously flows toward the poles. The constant motion of air transfers heat from the equator toward the poles, and as the air returns, it cools the land over which it passes. This continuous turnover moderates temperatures over Earth's surface.

The atmosphere exhibits complex horizontal movements In addition to global circulation patterns, the atmosphere exhibits complex horizontal movements called **winds**. The nature of wind, with its turbulent gusts, eddies, and lulls, is difficult to understand or predict. It results in part from differences in atmospheric temperature and pressure changes, Earth's rotation, and uneven heating of the oceans and continents.

The gases that constitute the atmosphere have weight and exert a pressure that is, at sea level, about 1013 millibars (14.7 lb/in.²). Air pressure is variable, however, and changes with altitude, temperature, and humidity. Winds tend to blow from areas of high atmospheric pressure to areas of low pressure; the greater the difference and proximity between the high and low pressure areas, the stronger the wind.

Earth's rotation influences the direction that wind blows. Because Earth rotates from west to east, wind swerves to the right in the Northern Hemisphere and to the left in the Southern Hemisphere. This tendency of moving air to be deflected from its path by Earth's rotation is known as the **Coriolis effect**.

The global ocean covers most of Earth's surface

The global ocean is a huge body of salt water that surrounds the continents and covers almost three-fourths of Earth's surface. It is a single, continuous body of water, but geographers divide it into four sections separated by the continents: the Pacific, Atlantic, Indian, and Arctic Oceans. The Pacific Ocean, which covers one-third of Earth's surface and contains more than half of Earth's water, is the largest by far.

Winds drive surface ocean currents The persistent prevailing winds blowing over the ocean produce mass movements of surface ocean water known as **ocean currents** (FIG. 55-15). The

prevailing winds generate circular ocean currents called gyres. For example, in the North Atlantic, the tropical trade winds tend to blow toward the west, whereas the westerlies in the midlatitudes blow toward the east (see Fig. 55-14). This movement helps establish a clockwise gyre in the North Atlantic. Thus, surface ocean currents and winds tend to move in the same direction, although there are many variations on this general rule.

The Coriolis effect is partly responsible for the paths that surface ocean currents travel. Earth's rotation from west to east causes surface ocean currents to swerve to the right in the Northern Hemisphere, producing a clockwise gyre of water currents. In the Southern Hemisphere, ocean currents swerve to the left, producing a counterclockwise gyre.

The ocean interacts with the atmosphere The ocean and the atmosphere are strongly linked. Wind from the atmosphere affects the ocean currents, and heat from the ocean affects atmospheric circulation. One of the best examples of the interaction between the ocean and atmosphere is the **El Niño–Southern Oscillation (ENSO)** event. ENSO is a periodic warming of surface waters of the tropical eastern Pacific that alters both oceanic and atmospheric circulation patterns and results in unusual weather in areas far from the tropical Pacific. Normally, westward-blowing trade winds restrict the warmest waters to the western Pacific (near Australia). Every three to seven years, however, the trade winds weaken, and the warm water mass expands eastward to South America, raising surface temperatures in the eastern Pacific. Ocean currents, which normally flow westward in this area, slow down, stop altogether, or even reverse and go eastward. The phenomenon is called El Niño, which is Spanish for “the (Christ) child,” because the warming usually reaches the fishing grounds off Peru just before Christmas. Most ENSOs last from one to two years. La Niña (Spanish for “the girl”), the opposite phase, is the cold phase, of the ENSO cycle and occurs when cold ocean waters return.

An ENSO event changes biological productivity in parts of the ocean. The warmer sea-surface temperatures and accompanying changes in ocean circulation patterns off the west coast of South America prevent colder, nutrient-laden deeper waters from **upwelling** (coming to the surface) (FIG. 55-16). The lack of nutrients in the water results in a severe decrease in the populations of anchovies and many other marine fishes. Other species, such as shrimp and scallops, thrive during an ENSO event. Along the Pacific coast of North America, ENSO shifts the distribution of tropical fishes northward and even affects the salmon run in Alaska.

Climate profoundly affects organisms

Climate is the average weather conditions, plus extremes (records), that occur in a given place over a period of years. The two most important factors that determine an area's climate are temperature (both average temperature and temperature extremes) and precipitation (both average precipitation and seasonal distribution). Other climate factors include wind, humidity, fog, cloud cover, and lightning-caused wildfires. Unlike weather, which changes rapidly, climate generally changes slowly, over hundreds or thousands of years.

Figure 55-16 Upwelling

Coastal upwelling, where deeper waters come to the surface, occurs in the Pacific Ocean along the South American coast. Upwelling provides nutrients for microscopic algae, which in turn support a complex food web. Coastal upwelling weakens considerably during years with ENSO events, temporarily reducing fish populations.

Day-to-day variations, day-to-night variations, and seasonal variations are also important dimensions of climate that affect organisms. Latitude, elevation, topography, vegetation, distance from the ocean or other large bodies of water, and location on a continent or other landmass all influence temperature, precipitation, and other aspects of climate.

Earth has many different climates, and because they have been relatively constant for many years, organisms have adapted to them. The wide variety of organisms on Earth evolved in part because of the many different climates, ranging from cold, snow-covered, polar climates to hot, tropical climates where it rains almost every day.

Air and water movements and surface features affect precipitation patterns Precipitation varies from one location to another and has a profound effect on the distribution and kinds of organisms present. One of the driest places on Earth is in the Atacama Desert in Chile, where the average annual rainfall is 0.05 cm (0.02 in.). In contrast, Mawsynram in India, Earth's wettest spot, receives an average annual precipitation of 1187 cm (467 in.).

Differences in precipitation depend on several factors. The heavy-rainfall areas of the tropics result mainly from the uplifting of moisture-laden air. High surface-water temperatures (recall the enormous amount of solar energy striking the equator) cause the evaporation of vast quantities of water from tropical parts of the ocean. Prevailing winds blow the resulting moist, warm air over landmasses. Land surfaces warmed by the sun heat the air and cause moist air to rise. As it rises, the air cools, and its moisture-holding ability decreases. (Cool air holds

less water vapor than warm air.) When air reaches its saturation point, it cannot hold any additional water vapor; clouds form, and water is released as precipitation. The air eventually returns to the surface on both sides of the equator near the Tropics of Cancer and Capricorn (latitudes 23.5 degrees north and south, respectively). By then, most of the moisture has precipitated so that dry air returns to the equator. This dry air makes little biological difference over the ocean, but its lack of moisture produces some of the great subtropical deserts, such as the Sahara.

Air is also dried during long journeys over landmasses. Near the windward (side from which the prevailing wind blows) coasts of continents, rainfall may be heavy. However, in the temperate zones—the areas between the tropical and polar zones—continental interiors are usually dry because they are far from the ocean that replenishes water vapor in the air passing over it.

Mountains force air to rise, removing moisture from humid air. As it gains altitude, the air cools, clouds form, and precipitation typically occurs, primarily on the windward slopes of the mountains. As the air mass moves down on the other side of the mountain, it is warmed, and clouds then evaporate, thereby lessening the chance of precipitation of any remaining moisture. This situation exists on the west coast of North America, where precipitation falls on the western slopes of mountains that are close to the coast. The dry lands on the sides of the mountains away from the prevailing wind (in this case, east of the mountain range) are called **rain shadows** (FIG. 55-17).

Microclimates are local variations in climate Differences in elevation, in the steepness and direction of slopes, and therefore in exposure to sunlight and prevailing winds may produce local variations in climate known as **microclimates**, which are sometimes quite different from their overall surroundings. Patches of sun and shade on a forest floor, for example, produce a variety of microclimates for plants, animals, and microorganisms living there. The microclimate of an organism's habitat is of primary importance because it is the

Figure 55-17 Rain shadow

A rain shadow is the arid or semiarid land that occurs on the leeward side of a mountain. Such a rain shadow occurs east of the Cascade Range in Washington State. The western side of the range receives more than 500 cm of precipitation annually, whereas the eastern side receives 40 to 50 cm.

climate that an organism actually experiences and must cope with. (Keep in mind, however, that microclimates are largely affected by the regional climates in which they are located.)

Sometimes organisms modify their own microclimate. For example, trees modify the local climate within a forest so that in summer the temperature is usually lower, and the relative humidity greater, than outside the forest. The temperature and humidity beneath the litter of the forest floor differ still more; in the summer the microclimate of this area is considerably cooler and moister than the surrounding forest. As another example, many desert-dwelling animals burrow to avoid surface climate conditions that would kill them in minutes. The cooler daytime microclimate in their burrows permits them to survive until night, when the surface cools off and they come out to forage or hunt.

Fires are a common disturbance in some ecosystems

Wildfires, which are fires started by lightning, are an important ecological force in many geographic areas. Those areas most prone to wildfires have wet seasons followed by dry seasons. Vegetation that grows and accumulates during the wet season dries out enough during the dry season to burn easily. When lightning hits vegetation or ground litter, it ignites the dry organic material, and a fire spreads through the area.

Fires have several effects on organisms. First, combustion frees the minerals that were locked in dry organic matter. The ashes remaining after a fire are rich in potassium, phosphorus, calcium, and other minerals essential for plant growth. With the arrival of precipitation, vegetation flourishes following a fire. Second, fire removes plant cover and exposes the soil. This change stimulates the germination and establishment of seeds requiring bare soil as well as encourages the growth of shade-intolerant plants. Third, fire causes increased soil erosion because it removes plant cover, leaving the soil more vulnerable to wind and water.

African savanna, California chaparral, North American grasslands, and ponderosa pine forests of the western United States are some fire-adapted ecosystems (see Chapter 56). Fire helps maintain grasses as the dominant vegetation in grasslands by removing fire-sensitive hardwood trees.

Humans try to prevent fires, and sometimes this effort has disastrous consequences. When fire is excluded from a fire-adapted ecosystem, deadwood and other plant litter accumulate. As a result, when a fire does occur, it can be very destructive. The sometimes deadly wildfires in Colorado and other western states and provinces are blamed in part on decades of suppressing fires in the region. Prevention of fire also converts grassland to woody vegetation and facilitates the invasion of fire-sensitive trees into fire-adapted forests.

Controlled burning is a tool of ecological management in which the undergrowth and plant litter are deliberately burned under controlled conditions before they have accumulated to dangerous levels (FIG. 55-18). Controlled burns are also used to suppress fire-sensitive trees, thereby maintaining the natural fire-adapted ecosystem. In a 2010 study of fire reintroduction in Sierra Nevada forests reported in *Ecosphere*, Karen Webster and Charles Halpern explored two decades of changes

MICHAEL FAY/National Geographic Creative

Figure 55-18 Controlled burn as a tool of ecological management

This aerial view of a controlled burn shows the leading edge of the fire, or fire line.

in plant diversity and abundance following reintroduction and repeated use of fire in previously unmanaged forests. Results from their research suggest that repeated controlled burning can gradually enhance the diversity and abundance of understory species and may enhance the dispersal of those species impacted by fire exclusion. More research needs to be conducted on when controlled burning is appropriate or how often it should be carried out. Moreover, there are major practical, political, and educational issues that must be addressed in implementing controlled burns.

CHECKPOINT 55.3

- What basic forces determine the circulation of the atmosphere?
- What basic forces produce the main ocean currents?
- **CONNECT** What are some of the factors that produce regional differences in precipitation?

55.4 Studying Ecosystem Processes

LEARNING OBJECTIVE

- 9 Briefly describe some of the long-term ecological research conducted at Hubbard Brook Experimental Forest.

Ecologists conduct detailed ecosystem studies in laboratory simulations and in the field to measure such processes as energy flow, the cycling of nutrients, and the effects of natural and human-induced disturbances (e.g., air pollution, tree harvesting, and land-use changes). Some ecosystem studies, such as those performed at the Hubbard Brook Experimental Forest (HBEF), a 3100-hectare (7750-acre) reserve in the White Mountain National Forest in New Hampshire, are long term (**FIG. 55-19**). Beginning in the late 1950s and continuing to the present, HBEF has been the site of numerous studies that address the hydrology (e.g., precipitation, surface runoff, and groundwater flow), biology, geology, and chemistry of forests and associated aquatic ecosystems. The National Science Foundation (NSF) has designated HBEF as one of its 24 long-term ecological research sites.

Many of the experiments at HBEF are based on field observations. For example, salamander populations were originally surveyed in forest communities in 1970 and have been resurveyed in recent years. Other studies involve manipulative experiments. In 1978, scientists added dilute sulfuric acid to a small stream in HBEF to study the chemical and biological effects of acidification. This experiment was of practical value because acid precipitation, a form of air pollution, has acidified numerous lakes and streams in industrialized countries.

Several researchers have studied the effects on HBEF stream ecosystems of **deforestation**, the clearance of large expanses of forest for agriculture or other uses. When a forest is removed, the total amount of water and minerals that flow into streams increases drastically. A concrete dam called a *catchment* can be constructed across a stream so that ecologists can measure the flow of water and chemical components out of the ecosystem. Catchments help scientists to measure the

These students are using a permeameter to measure water infiltration. This process allows them to estimate the hydraulic conductivity of the soil. Hubbard Brook Research Foundation, New Hampshire.

quantity, timing, and quality of water flowing from a forested watershed. Typically, outflow is measured in two separate ecosystems: one serves as a control, and one is experimentally manipulated. These studies demonstrate that deforestation causes soil erosion and leaching of essential minerals that result in decreased soil fertility. The summer temperatures in streams running through deforested areas are higher than in shady streams running through uncut forests. Many stream organisms do not fare well in deforested areas, in part because they are adapted to cooler temperatures.

Detailed studies such as those at HBEF provide ecologists with insights into how ecological processes function in individual ecosystems. Ecologists compare these data with similar information from other ecosystem studies to develop generalized insights into how ecosystems are structured and how they function. Long-term ecosystem experiments enable ecologists to evaluate and predict the effects of environmental change, including human-induced change.

Ecosystem experiments also contribute to our practical knowledge about how to maintain water quality, wildlife habitat, and productive forests. **Ecosystem management**, a conservation approach that emphasizes restoring and maintaining

the quality of an entire ecosystem rather than the conservation of individual species, makes use of such knowledge.

Ecologists are also studying the causes of food-web flips and ecosystem collapse to recognize tipping points. A *food-web flip* occurs when there is a major persistent change in the sequences of organisms eating and being eaten by one another. As reported in *Science*, a team from the University of Wisconsin–Madison led by Stephen Carpenter examined 30 years of research on Peter Lake, Wisconsin, and developed mathematical models to recognize early signs of tipping points. The researchers identified signs of change in an endangered food web 15 months before it flipped. Continued research in this area may enhance our ability to recognize warning signs to protect ecosystems from natural and human effects before irreversible or costly damage occurs.

CHECKPOINT 55.4

- What are some of the environmental effects observed in the deforestation study at Hubbard Brook Experimental Forest?

Summary: Focus on Learning Objectives

55.1 Energy Flow through Ecosystems (page 1195)

1 Summarize the concept of energy flow through a food web.

- Energy flow** through an ecosystem is linear, from the sun to producer to consumer to decomposer. Much of this energy is converted to heat as it moves from one organism to another, so organisms occupying the next **trophic level** cannot use it.
- Trophic relationships may be expressed as **food webs**, which show the many alternative pathways that energy may take among the producers, consumers, and decomposers of an ecosystem.

2 Explain typical pyramids of numbers, biomass, and energy.

- Ecological pyramids** typically express the progressive reduction in numbers of organisms, biomass, and energy found in successive trophic levels. A **pyramid of numbers** shows the number of organisms at each trophic level in a given ecosystem. A **pyramid of biomass** shows the total biomass at each successive trophic level. A **pyramid of energy** indicates the energy content of the biomass of each trophic level. Toxins can pass through food webs, cause serious health concerns, and remain an environmental threat for decades.

3 Distinguish between gross primary productivity and net primary productivity.

- **Gross primary productivity (GPP)** of an ecosystem is the rate at which photosynthesis captures energy. **Net primary productivity (NPP)** is the energy that remains (as biomass) after plants and other producers carry out cellular respiration.

55.2 Cycles of Matter in Ecosystems (page 1201)

4 Describe the main steps in each of these biogeochemical cycles: the carbon, nitrogen, phosphorus, and hydrologic cycles.

- Carbon dioxide is the important gas of the **carbon cycle**. Carbon enters plants, algae, and cyanobacteria as CO_2 , which photosynthesis incorporates into organic molecules. Cellular respiration, combustion, and erosion of limestone return CO_2 to the water and atmosphere, where it is again available to producers.
- The **nitrogen cycle** has five steps. **Nitrogen fixation** is the conversion of nitrogen gas to ammonia. **Nitrification** is the conversion of ammonia or ammonium to nitrate. **Assimilation** is the conversion of nitrates, ammonia, or ammonium to proteins and other nitrogen-containing compounds by plants; conversion of plant proteins into animal proteins is also assimilation. **Ammonification** is the conversion of organic nitrogen to ammonia and ammonium ions. **Denitrification** is the conversion of nitrate to nitrogen gas.
- The **phosphorus cycle** has no biologically important gaseous compounds. Phosphorus erodes from rock as inorganic phosphate, which the roots of plants absorb from the soil. Animals obtain the phosphorus they need from their diets. Decomposers release inorganic phosphate into the environment. When phosphorus washes into the ocean and is subsequently deposited in seabeds, it is lost from biological cycles for millions of years.
- The **hydrologic cycle** involves an exchange of water between the land, ocean, atmosphere, and organisms. Water enters the atmosphere by evaporation and **transpiration** and leaves the atmosphere as precipitation. On land, water filters through the ground or runs off to lakes, rivers, and the ocean. Aquifers are underground caverns and porous layers of rock in which groundwater is stored.

55.3 Abiotic Factors in Ecosystems (page 1206)

5 Summarize the effects of solar energy on Earth's temperatures.

- Of the solar energy that reaches Earth, 30% is immediately reflected away; the atmosphere and surface absorb the

remaining 70%. Ultimately, all absorbed solar energy is reradiated into space as infrared (heat) radiation.

- A combination of Earth's roughly spherical shape and the tilted angle of its axis concentrates solar energy at the equator and dilutes it at the poles; the tropics are hotter and less variable in climate than are temperate and polar areas.

6 Discuss the roles of solar energy and the Coriolis effect in the generation of global air and water flow patterns.

- Visible light and some infrared radiation warm the surface and the lower part of the atmosphere. Atmospheric heat transferred from the equator to the poles produces movement of warm air toward the poles and of cool air toward the equator.
- **Winds** result in part from differences in atmospheric pressure and from the **Coriolis effect**, the tendency of moving air or water, because of Earth's rotation, to be deflected to the right in the Northern Hemisphere and to the left in the Southern Hemisphere.
- Surface **ocean currents** result in part from prevailing winds and the Coriolis effect.

7 Give two causes of regional precipitation differences.

- Latitude, elevation, topography, vegetation, distance from the ocean or other large bodies of water, and location on a continent or other landmass influence precipitation.
- Precipitation is greatest where warm air passes over the ocean, absorbs moisture, and then cools, such as in areas where mountains force humid air upward. Deserts develop in the **rain shadows** of mountain ranges or in continental interiors.

8 Discuss the effects of fire on certain ecosystems.

- Fire frees the minerals locked in dry organic matter, removes plant cover and exposes the soil, and increases soil erosion. Many ecosystems, such as savanna, chaparral, grasslands, and certain forests, contain fire-adapted organisms.

55.4 Studying Ecosystem Processes (page 1212)

9 Briefly describe some of the long-term ecological research conducted at Hubbard Brook Experimental Forest.

- Hubbard Brook Experimental Forest (HBEF) in New Hampshire is the site of numerous long-term studies that address the hydrology (precipitation, surface runoff, and groundwater flow), biology (effects of deforestation and changes in salamander populations), geology, and chemistry (acid precipitation) of forests and associated aquatic ecosystems.

Test Your Understanding

Know and Comprehend

- The movement of matter is _____ in ecosystems, and the movement of energy is _____. (a) linear; linear (b) linear; cyclic (c) cyclic; cyclic (d) cyclic; linear (e) cyclic; linear or cyclic
- A complex of interconnected food chains in an ecosystem is called (a) an ecosystem (b) a pyramid of numbers (c) a pyramid of biomass (d) a biosphere (e) a food web
- The quantitative estimate of the total amount of living material is called (a) biomass (b) energy flow (c) gross primary productivity (d) plant respiration (e) net primary productivity
- Which of the following equations shows the relationship between gross primary productivity (GPP) and net primary productivity (NPP)?
(a) $GPP = NPP - \text{photosynthesis}$
(b) $NPP = GPP - \text{photosynthesis}$
(c) $GPP = NPP - \text{plant respiration}$
(d) $NPP = GPP - \text{plant respiration}$
(e) $NPP = GPP - \text{animal respiration}$
- Which of the following processes increase(s) the amount of atmospheric carbon in the carbon cycle? (a) photosynthesis (b) cellular respiration (c) combustion (d) a and c (e) b and c
- In the nitrogen cycle, gaseous nitrogen is converted to ammonia during (a) nitrogen fixation (b) nitrification (c) assimilation (d) ammonification (e) denitrification
- The conversion of ammonia to nitrate, known as _____, is a two-step process performed by soil bacteria. (a) nitrogen fixation (b) nitrification (c) assimilation (d) ammonification (e) denitrification
- Which biogeochemical cycle does not have a gaseous component but cycles from the land to sediments in the ocean and back to the land? (a) carbon cycle (b) nitrogen cycle (c) phosphorus cycle (d) hydrologic cycle (e) neither a nor c has a gaseous component
- Which of the following processes is not directly involved in the hydrologic cycle? (a) transpiration (b) evaporation (c) precipitation (d) nitrification (e) condensation
- The periodic warming of surface waters of the tropical eastern Pacific that alters both oceanic and atmospheric circulation patterns is known as (a) upwelling (b) prevailing wind (c) ocean current (d) El Niño–Southern Oscillation (e) Coriolis effect
- A mountain range may produce a downwind arid (a) upwelling (b) rain shadow (c) ocean current (d) microclimate (e) ecological pyramid

Apply and Analyze

- VISUALIZE** Draw the simplest stable ecosystem you can imagine.

- PREDICT** How might a food web change if all decomposers were eliminated from it?
- Why is the cycling of matter essential to the long-term continuance of life?
- What would happen to the nitrogen cycle if all bacteria were absent? Explain your answer.

Evaluate and Synthesize

- Would the microclimate of an ant be the same as that of an elephant living in the same area? Why or why not?
- INTERPRET DATA** Examine Figure 55-3b (*shown here*). Explain why this pyramid of biomass is inverted. In other words, how can 4 g of producers support 21 g of primary consumers?

- INTERPRET DATA** Scientists have compiled databases of large forest wildfires in the western United States and compared them to climate and land-surface data. Examine the graph showing wildfire frequency compared to average spring–summer temperature. Do you see a correlation? If so, describe it. Based on these data, do you think that climate warming is causing more wildfires? Explain your answer.

Adapted from Westerling, A.L., H.G. Hidalgo, D.R. Cayan, and T.W. Swetnam, "Warming and Earlier Spring Increase Western U.S. Forest Wildfire Activity," *Science*, Vol. 313 (Aug. 18, 2006).

- SCIENCE, TECHNOLOGY, AND SOCIETY** How do humans alter the nitrogen cycle, and what can scientists, engineers, and the public do to mitigate the damage?

56 Ecology and the Geography of Life

KEY CONCEPTS

- 56.1** Climate, particularly temperature and precipitation, affects the distribution of Earth's major biomes, such as tropical rain forests and tundra.
- 56.2** Abiotic factors—such as water salinity, amount of dissolved oxygen, availability of essential minerals, light, and water depth—influence the distribution of organisms in aquatic ecosystems.
- 56.3** Ecotones—areas of transition where two communities meet and intergrade—provide diverse conditions that encourage species richness.
- 56.4** Earth has several biogeographic realms, each consisting of a major landmass separated by deep water, mountains, or a desert.

PHOTO: Black-tailed prairie dogs. Prairie dogs (*Cynomys ludovicianus*) never wander far from their burrows, which they use to escape from predators. [scooperdigital/shutterstock.com](https://www.shutterstock.com)

Earth has many different environments. *Natural selection* affects an organism's ability to survive and reproduce in a given environment. In natural selection both **abiotic** (nonliving) and **biotic** (living) factors eliminate the least-fit individuals in a population. Over time, succeeding generations of organisms that live in each biome or major aquatic ecosystem become better adapted to local environmental conditions.

Black-tailed prairie dogs are superbly adapted to the biotic and abiotic factors of their environment. Their teeth and digestive tracts are modified to eat and easily digest the seeds and leaves of grasses that grow in great profusion on the Great Plains of western North America.

Prairie dogs live in large colonies of about 500 individuals. The eyes of every individual in the colony watch for potential danger, and when they see it, prairie dogs call out to warn the rest of the colony (see photograph). When danger approaches, each prairie dog dives into its underground home. Each burrow has at least two openings and consists of an elaborate network of long tunnels with several chambers: a nursery for the young, a sleeping chamber, a toilet chamber, and a listening chamber (close to an entrance). Piles of excavated soil surround the burrow entrances and help prevent flooding during rainstorms.

To survive winter, black-tailed prairie dogs sleep in their burrows. Their metabolism slows, and they subsist on the stored fat in their bodies. They do not truly hibernate, however, and may leave their burrows to look for food when the weather warms.

Like prairie dogs, each species has structural, behavioral, and physiological adaptations for its own particular environment. As you examine Earth's major terrestrial and aquatic ecosystems, including the species characteristic of each, think about the variety of adaptations that natural selection has produced in organisms in response to their particular environments.

56.1 Biomes

LEARNING OBJECTIVES

- 1 Define *biome* and briefly describe the nine major terrestrial biomes, giving attention to the climate, soil, and characteristic plants and animals of each.
- 2 Describe at least one human effect on each of the biomes discussed.

A **biome** is a large, relatively distinct terrestrial region that has similar climate, soil, plants, and animals regardless of where it occurs. Because it covers such a large geographic area, a biome encompasses many interacting landscapes. Recall from Chapter 53 that a **landscape** is a large land area (several to many square kilometers) composed of interacting ecosystems.

Biomes largely correspond to major climate zones, with temperature and precipitation being most important (FIG. 56-1). Near the poles, temperature is generally the overriding climate factor. In tropical and temperate regions, precipitation

Key Point

The distribution of the world's biomes is largely the result of climate patterns, which determine an area's water (measured as precipitation) and energy (measured as temperature).

Figure 56-1 Using precipitation and temperature to identify biomes

Factors such as soil type, fire, and seasonality of climate affect whether temperate grassland or chaparral develops. Adapted from R.H. Whittaker, *Communities and Ecosystems*, 2nd ed. (Macmillan, New York, 1975).

PREDICT As global climate continues to change, how might Earth's biomes be affected?

becomes more significant than temperature. Other abiotic factors to which biomes are sensitive include temperature extremes, rapid temperature changes, floods, droughts, strong winds, and fires (see section on fires in Chapter 55).

We discuss nine major biomes in this chapter: tundra, boreal forest, temperate rain forest, temperate deciduous forest, temperate grassland, chaparral, desert, savanna, and tropical rain forest. Although we discuss each biome as a distinct entity, biomes intergrade into one another at their boundaries.

Tundra is the cold, boggy plains of the far north

Tundra (also called **arctic tundra**) occurs in extreme northern latitudes wherever snow melts seasonally (FIG. 56-2). In the Southern Hemisphere, the **Antarctic tundra**, located on the Antarctic Peninsula and nearby islands, is home to animals such as penguins and elephant seals. Plant life in this warmer, slightly moister region of Antarctica consists of many mosses and lichens and some liverworts and fungi, but only two species of vascular plants. A third similar ecosystem, located in the higher elevations of mountains, above the tree line, is called **alpine tundra** (see *Inquiring About: The Distribution of Vegetation on Mountains*).

Arctic tundra has long, harsh winters and extremely short summers. Although the growing season, with its warmer temperatures, is as short as 50 days, the days are long. Above the Arctic Circle, the sun does not set at all for many days in midsummer. However, the amount of light at midnight is only one-tenth that at noon. There is little precipitation (10 to 25 cm, or 4 to 10 in., per year) over much of the tundra, and most of it falls during summer months.

Figure 56-2 Arctic tundra

Because of the short growing season and permafrost in arctic tundra, only small, hardy plants grow in this northernmost biome that encircles the Arctic Ocean. Photographed during autumn in Alaska.

Inquiring About

The Distribution of Vegetation on Mountains

Does the type of vegetation change at different elevations on a mountain? Hiking up a mountain is similar to traveling toward the North Pole with respect to the major life zones encountered (see figure). This elevation—latitude similarity occurs because the temperature drops as one climbs a mountain, just as it does when one travels north; the temperature drops about 6°C (11°F) with each 1000-m increase in elevation. The types of species growing on the mountain change as the temperature changes.

Deciduous trees, which shed their leaves every autumn, may cover the base of a mountain in Colorado, for example. At higher elevations, where the climate is colder and more severe, a coniferous *subalpine forest* resembling boreal forest grows. Spruces and firs are the dominant trees here.

Higher still, the forest thins, and the trees become smaller, gnarled, and shrublike. These twisted, shrublike trees, called *krummholz* (a German word meaning “crooked wood”), are found at their elevational limit (the *tree line*). The exact elevation at which the tree line occurs depends on the latitude and distance from the ocean. In the Rocky Mountains, between 35° and 50° north latitude, the tree line drops 100 m with each 1° latitude northward.

Above the tree line, where the climate is quite cold, a kind of tundra occurs, with vegetation composed of grasses, sedges, and small tufted plants, most of which are hardy perennials. Some alpine plants (e.g., buttercups) are lowland species that have adapted to the alpine environment, whereas other plants (e.g., mountain douglasia) live exclusively in the mountains. This tundra is called *alpine tundra* to distinguish it from arctic tundra. At the top of the mountain, a permanent ice

cap or snowcap might be found, similar to the nearly lifeless polar land areas.

Important environmental differences exist between high elevations and high latitudes that affect the types of organisms found in each place. Alpine tundra typically lacks permafrost and receives more precipitation than does arctic tundra. High elevations of temperate mountains do not have the great

extremes of day length that are associated with the changing seasons in high-latitude biomes. The intensity of solar radiation is greater at high elevations than at high latitudes. At high elevations, the sun’s rays pass through less atmosphere, which results in greater exposure to ultraviolet radiation (less is filtered out by the atmosphere) than occurs at high latitudes.

Comparison of elevation and latitude zones. The cooler temperatures at higher elevations of a mountain produce a series of ecosystems similar to those encountered when going toward the North Pole.

Tundra soils tend to be geologically young (with the exception of Antarctic tundra) because most were formed only after the last Ice Age.¹ These soils are usually nutrient poor and have little organic litter (dead leaves and stems, animal droppings, and remains of organisms) in the uppermost layer of soil. Although the soil surface melts during the summer, tundra has a layer of permanently frozen ground called **permafrost** that varies in depth and thickness. Because permafrost interferes with drainage, the thawed upper zone of soil is usually waterlogged during the summer. Limited precipitation, combined with low temperatures, flat topography (surface features), and

permafrost, produces a landscape of broad, shallow lakes, sluggish streams, and bogs. Many scientists are concerned that global warming is accelerating the melting of permafrost, resulting in a rapidly increasing release of carbon dioxide and methane (another potent greenhouse gas) into the atmosphere.

Low species richness and low primary productivity characterize tundra. Mosses, lichens (such as reindeer moss), grasses, and grasslike sedges dominate tundra vegetation. Most of these short plants are herbaceous perennials that live 20 to 100 years. No readily recognizable trees or shrubs grow except in sheltered locations. However, dwarf willows, dwarf birches, and other dwarf trees are common.

Year-round animal life of the tundra includes voles, weasels, arctic foxes, gray wolves, snowshoe hares, ptarmigan, snowy owls, musk oxen, and lemmings (see Figure 53-5 and

¹ Glacier ice, which occupied about 30% of Earth’s land during the last Ice Age, began retreating about 17,000 years ago. Today, glacier ice occupies about 10% of the land surface.

the discussion of lemming population cycles in Chapter 53). In the summer, caribou migrate north to the tundra to graze on sedges, grasses, and dwarf willow. Dozens of bird species also migrate north in summer to nest and feed on abundant insects. Mosquitoes, blackflies, and deerflies survive the winter as eggs or pupae and occur in great numbers during summer weeks.

Tundra regenerates quite slowly after it has been disturbed. Even casual recreational use causes damage and pollution. Long-lasting injury, likely to persist for hundreds of years, has been done to large portions of the arctic tundra as a result of oil and gas exploration, road and pipe construction, and military use.

Boreal forest is the evergreen forest of the north

Just south of the tundra lies the **boreal forest**, also known as **coniferous forest** or **taiga**. (Conifers are cone-bearing evergreens.) The boreal forest, which stretches across both North America and Eurasia, is the world's largest terrestrial biome, covering about 10% of Earth's land (FIG. 56-3). A biome comparable to the boreal forest is not found in the Southern Hemisphere because it has no land at the corresponding latitudes. Winters are extremely cold and severe, although not as harsh as in the tundra. Boreal forest receives little precipitation, perhaps 50 cm (20 in.) per year. Its soil is typically acidic, low in minerals (inorganic nutrients), and has a deep layer of partly decomposed conifer needles at the surface. Boreal forest contains numerous ponds and lakes in water-filled depressions dug by grinding ice sheets during the last Ice Age.

White and black spruces, balsam fir, eastern larch, and other conifers dominate the boreal forest. However, **deciduous** trees such as aspen or birch, which shed their leaves in autumn, form striking stands. Conifers have many drought-resistant adaptations, such as needlelike leaves with a minimal surface area to reduce water loss (see Fig. 34-9). Such an adaptation enables conifers to withstand the "drought" of the northern winter

Figure 56-3 Boreal forest

Boreal forest is coniferous forest that occurs in cold regions of the Northern Hemisphere adjacent to the tundra. Photographed in Banff National Park, Canada.

months, when roots do not absorb water because the ground is frozen. Natural selection also favors conifers in the boreal forest because, being evergreen, they resume photosynthesis as soon as warmer temperatures return.

Animal life of the boreal forest includes some larger species, such as caribou (which migrate from the tundra to the boreal forest for winter), wolves, bears, and moose. However, most animal life is medium-sized to small and includes rodents, rabbits, and fur-bearing predators such as lynx, sable, and mink. Most species of birds are seasonally abundant but migrate to warmer climates for winter. Insects are numerous, but there are few amphibians and reptiles except in the southern boreal forest.

Most of the boreal forest is not suitable for agriculture because of its short growing season and mineral-poor soil. The boreal forest, which is harvested primarily by clear-cutting, is currently the primary source of the world's industrial wood and wood fiber.

Temperate rain forest has cool weather, dense fog, and high precipitation

Coniferous **temperate rain forest** grows on the northwestern coast of North America. Similar vegetation exists in southeastern Australia and in southwestern South America. Annual precipitation in this biome is high, from 200 to 380 cm (80 to 150 in.). Condensation of water from dense coastal fog augments the annual precipitation. The proximity of temperate rain forest to the coastline moderates the temperature so that seasonal fluctuation is narrow; winters are mild, and summers are cool. Temperate rain forest has a relatively nutrient-poor soil, although its organic content may be high. Cool temperatures slow the activity of bacterial and fungal decomposers. Thus, needles and large fallen branches and trunks accumulate on the ground as litter. It takes many years for the litter to decay and release inorganic minerals to the soil.

The dominant vegetation type found in the North American temperate rain forest is large evergreen trees, such as western hemlock, Douglas fir, Sitka spruce, and western red cedar. Temperate rain forest is rich in epiphytic vegetation, which consists of smaller plants that grow nonparasitically on the trunks and branches of large trees (FIG. 56-4). Epiphytes in this biome are mainly mosses, lichens, and ferns, all of which also carpet the ground. Squirrels, wood rats, mule deer, elk, numerous bird species (such as jays, nuthatches, and chickadees), several species of reptiles (such as painted turtles and western terrestrial garter snakes), and amphibians (such as Pacific giant salamanders and Pacific treefrogs) are common temperate rainforest animals.

Temperate rain forest, one of the richest wood producers in the world, supplies us with lumber and pulpwood. It is also one of the most complex ecosystems in terms of species richness. Care must be taken to avoid overharvesting original old-growth forest because such an ecosystem takes hundreds of years to develop. When the logging industry harvests old-growth forest, it typically replants the area with a monoculture (a single species) of trees that it harvests in 40- to 100-year cycles. Thus, the old-growth forest ecosystem, once harvested, never has a chance to redevelop. Less than 10% of the original,

Figure 56-4 Temperate rain forest

Large amounts of precipitation characterize temperate rain forest. Note the epiphytes hanging from the branches of coniferous trees. Photographed in Olympic National Park in Washington State.

old-growth temperate rain forest in Washington, Oregon, and northern California remains untouched. These stable forest ecosystems provide biological habitat for many organisms, including more than 50 endangered and threatened species.

Temperate deciduous forest has a canopy of broad-leaf trees

Seasonality (hot summers and cold winters) is characteristic of **temperate deciduous forest**, which occurs in temperate areas where precipitation ranges from about 75 to 126 cm (30 to 50 in.) annually. Typically, the soil of a temperate deciduous forest consists of both a topsoil rich in organic material and a deep, clay-rich lower layer. As organic materials decay, mineral ions are released. If roots of living trees do not absorb these ions, they leach into the clay, where they may be retained.

Broad-leaf hardwood trees, such as oak, hickory, maple, and beech, which lose their foliage annually, dominate temperate deciduous forests of the northeastern and Mid-Atlantic United States and much of Central Europe (**FIG. 56-5**). The trees of the temperate deciduous forest form a dense canopy that overlies saplings and shrubs.

Temperate deciduous forests in North America originally contained a variety of large mammals such as mountain lions, wolves, bison, and other species now regionally extinct, plus

Figure 56-5 Temperate deciduous forest

The broad-leaf trees that dominate the temperate deciduous forest shed their leaves before winter. Photographed during autumn at the Durance River in France.

deer, bears, and many small mammals and birds (such as wild turkeys, blue jays, and scarlet tanagers). Both reptiles (such as box turtles and rat snakes) and amphibians (such as spotted salamanders and wood frogs) abounded, together with a denser and more varied insect life than exists today.

In Europe and North America, logging and land clearing for farms, tree plantations, and cities have removed much of the original temperate deciduous forest. Where it has regenerated, temperate deciduous forest is often in a seminatural state, highly modified by humans for recreation, livestock foraging, timber harvest, and other uses. Although these returning forests do not have the biological diversity of virgin stands, many forest organisms have successfully become re-established. For example, in the eastern United States, white-tailed deer populations were decimated by hunting by 1900. As large parts of forests were modified for agricultural use and large predators (wolves and panthers) were eliminated, the white-tailed deer population rebounded. In fact, many regions now consider the animals an agricultural or suburban nuisance and have increasingly invested in research to monitor and manage the deer population.

Worldwide, temperate deciduous forest was among the first biomes to be converted to agricultural use. In Europe and Asia, many soils that originally supported temperate deciduous forest have been cultivated by traditional agricultural methods for thousands of years without a substantial loss in fertility. During the 20th century, however, intensive agricultural practices were adopted. Along with overgrazing and deforestation, these methods have contributed to the degradation of some agricultural lands.

Temperate grasslands occur in areas of moderate precipitation

Summers are hot, winters are cold, fires help shape the landscape, and rainfall is often uncertain in **temperate grasslands**. Annual precipitation averages 25 to 75 cm (10 to 30 in.). In grasslands with less precipitation, minerals tend to accumulate in a marked layer just below the topsoil. These minerals tend to leach out of the soil in areas with more precipitation. Grassland soil contains considerable organic material because surface

Figure 56-6 Temperate grassland

The Nature Conservancy owns this tallgrass prairie preserve in Oklahoma. Like other moist temperate grasslands, it is mostly treeless but contains a profusion of grasses and other herbaceous flowering plants. As bison graze on the plants, they affect community structure and diversity.

parts of many grasses die off each winter and contribute to the organic content of the soil (the roots and rhizomes survive underground). Many grasses are sod formers: their roots and rhizomes form a thick, continuous underground mat.

Moist temperate grasslands, also known as *tallgrass prairies*, occur in the United States in Iowa, western Minnesota, eastern Nebraska, and parts of other midwestern states and across Canada's prairie provinces. Although few trees grow except near rivers and streams, grasses, some as tall as 2 m (6.5 ft), grow in great profusion in the deep, rich soil (FIG. 56-6). Before most of this area was converted to arable land, it was covered with herds of grazing animals, particularly bison. The principal predators were wolves, although in sparser, drier areas, coyotes took their place. Smaller fauna included prairie dogs and their predators (foxes, black-footed ferrets, and birds of prey such as prairie falcons), western meadowlarks, bobolinks, reptiles (such as gopher snakes and short-horned lizards), and great numbers of insects.

Shortgrass prairies, in which the dominant grasses are less than 0.5 m (1.6 ft) tall, are temperate grasslands that receive less precipitation than the moister grasslands just described but more precipitation than deserts. In the United States, shortgrass prairies occur in the eastern half of Montana, the western half of South Dakota, and parts of other midwestern states; they also appear in western Alberta in Canada. The plants grow in less abundance than in the moister grasslands, and occasionally some bare soil is exposed.

The North American grassland, particularly the tallgrass prairie, was so well suited to agriculture that little of it

remains. More than 90% has vanished under the plow, and the remainder is so fragmented that almost nowhere can we see even an approximation of what European settlers saw when they settled in the Midwest. Today, the tallgrass prairie is considered North America's rarest biome.

In recent decades, woody shrubs and small trees such as juniper have invaded many of the world's grasslands in North and South America, Africa, and Australia. These plants displace native grasses, reducing the amount of food available for grazing animals. Fires in such altered ecosystems are more catastrophic, and the deep roots of these invasive plants tap into water, altering the area's water resources. Scientists are studying the roles that climate change, increased droughts, overgrazing, and fire suppression all play to better protect and manage the grasslands.

Chaparral is a thicket of evergreen shrubs and small trees

Some hilly temperate environments have mild winters with abundant rainfall combined with extremely dry summers. Such Mediterranean climates, as they are called, occur not only in the area around the Mediterranean Sea, but also in California, Western Australia, portions of Chile, and South Africa. In southern California, this environment is called **chaparral**. This vegetation type is also known as maquis in the Mediterranean region, mallee scrub in Australia, matorral in Chile, and Cape scrub in Africa. Chaparral soil is thin and infertile. Frequent fires occur naturally in this environment, particularly in late summer and autumn.

Chaparral vegetation looks strikingly similar in different areas of the world, even though the individual species are quite different. A dense growth of evergreen shrubs, often of drought-resistant pine or scrub oak trees, dominates chaparral (FIG. 56-7). During the rainy winter season, the landscape may be lush and green, but during the hot, dry summer, the plants lie dormant. Trees and shrubs often have hard, small, leathery leaves that resist water loss. Many plants are also fire-adapted and grow best in the months following a fire. Such growth is possible because fire releases minerals that were tied up in the plants that burned. With the new availability of essential minerals, plants sprout vigorously during winter rains. Mule deer, wood rats, brush rabbits, skinks and other

Verna Johnston/Science Source

Figure 56-7 Chaparral

Chaparral, which consists primarily of drought-resistant evergreen shrubs and small trees, develops where hot, dry summers alternate with mild, rainy winters. Photographed in the western Sierra Nevada foothills.

lizards, and many species of birds (such as Anna's hummingbird, scrub jay, and bushtit) are common animals of the chaparral.

Fires, which occur at irregular intervals in California chaparral vegetation, often consume expensive homes built on the hilly chaparral landscape. Unfortunately, efforts to control naturally occurring fires sometimes backfire. Denser, thicker vegetation tends to accumulate when periodic fires are prevented; then, when a fire does occur, it is much more severe. Also, more frequent fires, due to human activity, are driving ecosystem changes in which sensitive native species are being displaced by non-native weeds. The highly flammable weeds contribute to more severe fires, reducing biodiversity and converting chaparral to weedy wastelands. Removing the chaparral vegetation, whose roots hold the soil in place, also causes problems such as mud slides that sometimes occur during winter rains in these areas.

Deserts are arid ecosystems

Deserts are dry areas found in temperate (*cold deserts*) and subtropical or tropical regions (*warm deserts*). North America has four distinct deserts. The Great Basin Desert in Nevada, Utah, and neighboring states is a cold desert dominated by sagebrush. The Mojave Desert in Nevada and California is a warm desert known for its Joshua trees (a type of yucca with an erect, woody stem). The Chihuahuan Desert, home of century plants (agaves; see Fig. 53-7), is a warm desert found in Texas, New Mexico, and Mexico. The warm Sonoran Desert, with its many species of cacti, is found in Arizona, California, and Mexico (**FIG. 56-8**).

The low water-vapor content of the desert atmosphere leads to daily temperature extremes of heat and cold, so a major change in temperature occurs in each 24-hour period. Deserts vary greatly depending on the amount of precipitation they receive, which is generally less than 25 cm (10 in.) per year. A few deserts are so dry that virtually no plant life occurs in them. As a result of sparse vegetation, desert soil is low in organic material but often high in mineral content, particularly the salts NaCl , CaCO_3 , and CaSO_4 .

Desert vegetation includes both perennials (cacti, yuccas, Joshua trees, and sagebrushes) and, after a rain, flowering annuals. Desert plants tend to have reduced leaves or no leaves, an adaptation that conserves water. In cacti such as the giant saguaro, for example, the stem carries out photosynthesis and also expands accordion-style to store water; the leaves are modified into spines, which discourage herbivores. Other desert plants shed their leaves for most of the year, growing only during the brief moist season.

blickwinkel/Alamy Stock Photo

Figure 56-8 Desert

Summer rainfall characterizes the warmer deserts of North America, such as the Sonoran Desert shown here. The Sonoran Desert contains many species of cacti, including the large, treelike saguaro (*Carnegiea gigantea*), which grows 15 to 18 m (50 to 60 ft) tall. Photographed in Arizona.

Desert animals tend to be small. During the heat of the day, they remain under cover or return to shelter periodically, whereas at night they come out to forage or hunt. In addition to desert-adapted insects, there are many specialized desert reptiles (such as desert iguanas, desert tortoises, and rattlesnakes) and a few desert-adapted amphibians (such as western spadefoot toads). Mammals include rodents such as the American kangaroo rat, which does not need to drink water but subsists solely on the water content of its food (primarily seeds and insects). American deserts are also home to jackrabbits, and kangaroos live in Australian deserts. Carnivores such as the African fennec fox and some birds of prey, especially owls, live on rodents and rabbits. During the driest months of the year, many desert insects, amphibians, reptiles, and mammals tunnel underground, where they remain inactive; this period of dormancy is known as *estivation*.

Humans have altered North American deserts in several ways. Off-road vehicles damage desert vegetation, which sometimes takes years to recover. When the top layer of desert soil is disturbed, erosion occurs more readily than when the soil is undamaged, and less vegetation grows to support native animals. Another problem is that certain cacti and desert tortoises have become rare as a result of poaching. Houses, factories, and farms built in desert areas require vast quantities of water, which must be imported from distant areas. Irrigation of desert soils often causes them to become salty and unfit for crops or native vegetation. Increased groundwater consumption by many desert cities has caused groundwater levels to drop. Aquifer depletion in U.S. deserts is particularly critical in central and southern Arizona and southwestern New Mexico and is an increasing concern in southern California, Nevada, and Utah.

Savanna is a tropical grassland with scattered trees

The **savanna** biome is a tropical grassland with widely scattered clumps of low trees (FIG. 56-9). Savanna is found in areas of relatively low or seasonal rainfall with prolonged dry periods. Temperatures in savannas vary little throughout the year, and precipitation, not temperature (as in temperate grasslands), regulates seasons. Annual precipitation is 85 to 150 cm (34 to 60 in.). Savanna soil is low in essential minerals, in part because it is strongly leached. Savanna soil is often rich in aluminum, which resists leaching, and in places the aluminum reaches levels that are toxic to many plants. Although the African savanna is best known, savanna also occurs in South America and northern Australia.

Wide expanses of grasses interrupted by occasional trees characterize savanna. Trees such as *Acacia* bristle with thorns that provide protection against herbivores. Both trees and grasses have fire-adapted features, such as extensive underground root systems, that enable them to survive seasonal droughts as well as periodic fires that sweep through the savanna.

The world's greatest assemblage of hoofed mammals occurs in the African savanna. Here live great herds of herbivores, including wildebeests, antelopes, giraffes, zebras, and elephants. Large predators, such as lions and hyenas, kill and scavenge the herds. In areas of seasonally varying rainfall, the herds and their predators may migrate annually.

Savanna is rapidly being fragmented and converted to rangeland for cattle and other domesticated animals, which are replacing the big herds of wild animals. The problem is particularly acute in Africa, which has the most rapidly growing human population of any continent. In some places severe overgrazing by domestic animals has contributed to the conversion of marginal savanna into desert, a process known as **desertification**. In desertification the reduced grass cover caused by overgrazing allows wind and water to erode the soil; erosion removes the topsoil and decreases the soil's ability to support crops or livestock. Desertification has also become a serious problem in South America, Mexico, and the Caribbean due to overgrazing, farming, and drought. Satellite monitoring, in concert with local-level management, has shown promising results to reclaim fringe areas. (Desertification is not restricted to savanna. Temperate grasslands and tropical dry forests can also be degraded to desert.)

Figure 56-9 Savanna

In this photograph of African savanna in Tanzania, the smaller animals in the foreground are Thomson's gazelles (*Gazella thomsonii*), and the larger ones near the trees are wildebeests (*Connochaetes taurinus*).

There are two basic types of tropical forests

There are many kinds of tropical forests, but ecologists generally classify them as one of two types: tropical dry forests or tropical rain forests. **Tropical dry forests** occur in regions with a wet season and a dry season (usually two to three months each year). Annual precipitation is 150 to 200 cm (60 to 80 in.). During the dry season, many tropical trees shed their leaves and remain dormant, much as temperate trees do during the winter. India, Brazil, Thailand, and Mexico are some of the countries that have tropical dry forests. Tropical dry forests intergrade with savanna on their dry edges and with tropical rain forests on their wet edges. Logging and overgrazing by domestic animals have fragmented and degraded many tropical dry forests.

The annual precipitation of **tropical rain forests** is 200 to 450 cm (80 to 180 in.). Much of this precipitation, which occurs almost daily, comes from locally recycled water that enters the atmosphere by transpiration from the forest's own trees.

Tropical rain forests are often located in areas with ancient, highly weathered, mineral-poor soil. Little organic matter accumulates in such soils. Because temperatures are high and soil moisture is abundant year-round, decay organisms and detritus-feeding ants and termites decompose organic litter quite rapidly. Vast networks of roots and mycorrhizae quickly absorb minerals from decomposing materials. Thus, minerals of tropical rain forests are tied up in the vegetation rather than in the soil.

Tropical rain forests are found in Central and South America, Africa, and Southeast Asia. A tropical rain forest is very productive despite the scarcity of minerals in the soil. Its plants, stimulated by abundant solar energy and precipitation, capture considerable energy by photosynthesis. Of all the biomes, the tropical rain forest is unrivaled in species richness.

Most trees of tropical rain forests are evergreen flowering plants. A fully developed rain forest has several distinct stories of vegetation (**FIG. 56-10**). The topmost story, called the *emergent layer*, consists of the crowns of the oldest, tallest trees, some 40 m (130 ft) or more in height; these trees

Figure 56-10 Tropical rain forest

Tropical rainforest vegetation is stratified. Except at river banks, tropical rain forest has a closed canopy that admits little light to the forest floor. The animals highlighted in this figure occupy a variety of ecological niches in the rain forest. Adapted from Miller, G.T., and S.E. Spoolman, *Living in the Environment*, 17th ed. (Cengage/Brooks Cole, Belmont, CA, 2012): 162, Figure 7-15.

are exposed to direct sunlight and are subject to the warmest temperatures, lowest humidities, and strongest winds. The next story, the *canopy*, reaches a height of 30 to 35 m (100 to 115 ft). The canopy allows little sunlight for the support of the sparse *understory*, shrub layer, and ground layer. These layers all consist of smaller plants specialized for life in the shade, as well as seedlings of taller trees. Vegetation of tropical rain forests is generally not dense at ground level except near stream banks or where a fallen tree has opened the canopy.

Tropical rainforest trees support extensive epiphytic communities of smaller plants such as orchids and bromeliads. Although epiphytes grow in crotches of branches, on bark, or even on the leaves of their hosts, most use their host trees only for physical support, not for nourishment.

Because little light penetrates to the understory, many plants living there are adapted to climb already-established host trees. Lianas (woody tropical vines), some as thick as a human thigh, twist up through the branches of tropical rainforest trees. Once in the canopy, lianas grow from the upper branches of one tree to another, connecting the tops of the trees and providing a walkway for many of the canopy's residents.

Not counting bacteria and other soil-dwelling organisms, about 90% of tropical rainforest organisms live in the middle and upper canopies. Rainforest animals include the most abundant and varied insect, reptile, and amphibian fauna on Earth. Birds, too, are diverse, with some specialized to consume fruits (such as parrots), some to consume nectar (such as hummingbirds and sunbirds), and others to consume insects. Most rainforest mammals, such as sloths and monkeys, live only in the trees and never climb down to the ground. Some large ground-dwelling mammals, including elephants, are also found in tropical rain forests.

Unless strong conservation measures are initiated soon, human population growth and agricultural and industrial expansion in tropical countries may spell the end of tropical rain forests by the early 22nd century. Many rainforest species may become extinct before they are even identified and scientifically described. (Tropical rainforest destruction is discussed in detail in Chapter 57.)

To review, examine **FIGURE 56-11**, which shows the geographic distribution of the world's biomes.

CHECKPOINT 56.1

- **CONNECT** What climate and soil factors produce the major biomes?
- **CONNECT** What representative organisms are found in each of these forest biomes: boreal forest, temperate deciduous forest, temperate rain forest, and tropical rain forest?
- **CONNECT** In which biome do you live? Does it match the description given in this text? If not, explain the discrepancy.
- **CONNECT** How does tundra compare to desert? How does temperate grassland compare to savanna?

56.2 Aquatic Ecosystems

LEARNING OBJECTIVES

- 3 Explain the important environmental factors that affect aquatic ecosystems.
- 4 Distinguish among plankton, nekton, and benthos.
- 5 Briefly describe the various freshwater, estuarine, and marine ecosystems, giving attention to the environmental characteristics and representative organisms of each.
- 6 Describe at least one human effect on each of the aquatic ecosystems discussed.

The term *biome*, generally used to describe terrestrial environments based on dominant forms of vegetation, animals, and climate, does not adequately describe aquatic environments. Aquatic ecologists do not distinguish aquatic ecosystems based on the dominant form of vegetation. Instead, they use primarily abiotic factors, such as salinity, to determine an aquatic life zone's boundaries. **Salinity**, the concentration of dissolved salts in a body of water, affects the kinds of organisms present in aquatic ecosystems, as does the amount of dissolved oxygen. Because water greatly interferes with the penetration of light, floating aquatic organisms that photosynthesize remain near the water's surface, and vegetation attached to the bottom grows only in shallow water. In addition, low levels of essential minerals often limit the number and distribution of organisms in certain aquatic environments. Other abiotic determinants of species composition in aquatic ecosystems include water depth, temperature, pH, and presence or absence of waves and currents.

Aquatic ecosystems, both fresh water and marine, contain three main ecological categories of organisms: free-floating plankton, strongly swimming nekton, and bottom-dwelling benthos. **Plankton** are usually small or microscopic organisms that are relatively feeble swimmers. For the most part, they are carried about at the mercy of currents and waves. They are unable to swim far horizontally, but some species are capable of large vertical migrations and are found at different depths of water at different times of the day or at different seasons. Plankton are generally subdivided into two major categories: phytoplankton and zooplankton. **Phytoplankton** (photosynthetic cyanobacteria and free-floating algae) are

producers that form the base of most aquatic food webs. **Zooplankton** are nonphotosynthetic organisms that include protozoa, tiny crustaceans, and the larval stages of many animals. **Nekton** are larger, actively swimming organisms such as fishes, turtles, and whales. **Benthos** are bottom-dwelling organisms that fix themselves to one spot (sponges, oysters, and barnacles), burrow into the sand (many worms and echinoderms), or walk or swim about on the bottom (crayfish, aquatic insect larvae, and brittle stars).

Freshwater ecosystems are linked to land and marine ecosystems

Freshwater ecosystems include streams and rivers (flowing-water ecosystems), ponds and lakes (standing-water ecosystems), and marshes and swamps (freshwater wetlands). Each type of freshwater ecosystem has its own specific abiotic conditions and characteristic organisms. Although freshwater ecosystems occupy a relatively small portion—about 2%—of Earth's surface, they are important in the hydrologic cycle because they assist in recycling precipitation that flows as surface runoff to the ocean (see discussion of the hydrologic cycle in Chapter 55). Freshwater habitats also provide homes for many species.

Streams and rivers are flowing-water ecosystems

Many different conditions exist along the length of a stream or river (**FIG. 56-12**). The nature of a **flowing-water ecosystem** changes greatly from its source (where it begins) to its mouth (where it empties into another body of water). Headwater streams (small streams that are the sources of a river) are usually shallow, clear, cold, swiftly flowing, and highly oxygenated. In contrast, rivers downstream from the headwaters are wider and deeper, turbid (i.e., they contain suspended particulates), not as cold, slower flowing, and less oxygenated than headwater streams. Surrounding forest may shade certain parts of the stream or river, whereas other parts may be exposed to direct sunlight. Along parts of a stream or river, groundwater wells up through sediments on the bottom. This local input of water moderates the water temperature so that summer temperatures are cooler and winter temperatures are warmer than in adjacent parts of the flowing-water ecosystem.

The kinds of organisms in flowing-water ecosystems vary greatly from one stream to another, depending primarily on the strength of the current. In streams with fast currents, inhabitants have adaptations such as suckers to attach themselves to rocks so that they are not swept away. The larvae of blackflies, for example, attach themselves with suction discs located on the ends of their abdomens. Some stream inhabitants, such as immature water-penny beetles, have flattened bodies that enable them to slip under or between rocks. The water-penny beetle larva gets its common name from its flattened, nearly circular shape. Alternatively, inhabitants such as the brown trout are streamlined and muscular enough to swim in the current.

Streams and rivers depend on land for much of their energy. In headwater streams, up to 99% of the energy input comes from detritus (dead organic material such as leaves) carried from the land into streams and rivers by wind or surface runoff.

Figure 56-12 Features of a typical river

The river begins at a source, often high in mountains and fed by melting snows or glaciers. Headwater streams flow downstream rapidly, often over rocks (as rapids) or bluffs (as waterfalls). Along the way, tributaries feed into the river. As the river's course levels, the river flows more slowly and winds from side to side. Some of these winding streams may become cut off from the main river and become U-shaped oxbow lakes. The floodplain is the area on either side of the river that is subject to flooding. Near the ocean, the river may form a salt marsh where fresh water from the river and salt water from the ocean mix. Sediments deposited by the river as it empties into the ocean form the delta, a fertile, low-lying plain at the river's mouth. Rivers eventually empty into larger rivers or into the ocean. Adapted from Miller, G.T., and S.E. Spoolman, *Living in the Environment*, 17th ed. (Cengage/Brooks Cole, Belmont, CA, 2012): 183, Figure 8-18.

Downstream, rivers contain more producers and therefore depend slightly less on detritus as a source of energy than do the headwaters.

Human activities have several adverse effects on rivers and streams, including water pollution and the impacts of dams built to contain the water of rivers or streams. Pollution, such as sewage and fertilizer runoff, alters the physical environment of a flowing-water ecosystem and changes the biotic component downstream from the pollution source. Dams change the nature of flowing-water ecosystems, both upstream and downstream from the dam location. A dam causes water to back up, resulting in flooding of large areas of land and formation of a reservoir, which destroys terrestrial habitat. Below the dam, the once-powerful river is reduced to a relative trickle, so the flowing-water ecosystem is altered.

Ponds and lakes are standing-water ecosystems In contrast to moving water systems such as rivers, ponds, and lakes, **standing-water ecosystems** are characterized by zonation. A large lake has four basic zones: the littoral, limnetic, profundal, and benthic zones (FIG. 56-13). Smaller lakes and ponds typically lack a profundal zone.

The **littoral zone** is a shallow-water area along the shore of a lake or pond. It includes rooted, emergent vegetation, such as cattails and bur-reeds (flowering wetland plants), plus several deeper-dwelling aquatic plants and algae. The littoral zone is the most productive zone of the lake. Photosynthesis is greatest

in the littoral zone, in part because light is abundant and because the littoral zone receives nutrient inputs from surrounding land that stimulate the growth of plants and algae. In addition, ponds and lakes—like streams and rivers—depend on detritus carried from the land for much of their energy. Animals of the littoral zone include frogs and their tadpoles, turtles, worms, crayfish and other crustaceans, insect larvae, and many fishes such as perch, carp, and bass. Surface dwellers, such as water striders and whirligig beetles, are found in the quieter areas.

The **limnetic zone** is the open water beyond the littoral zone, that is, away from the shore; it extends down as far as sunlight penetrates to permit photosynthesis. The main organisms of the limnetic zone are microscopic phytoplankton and zooplankton. Larger fishes also spend some of their time in the limnetic zone, although they may visit the littoral zone to feed and reproduce. Because of the depth of this zone, less vegetation grows in the limnetic zone than in the littoral zone.

Beneath the limnetic zone of a large lake is the **profundal zone**. Because light does not penetrate effectively to this depth, plants and algae do not live in this zone. Food drifts into the profundal zone from the littoral and limnetic zones. Bacteria and archaea decompose dead plants and animals that reach the profundal zone, thus liberating minerals. These minerals are not effectively recycled because no photosynthetic organisms are present to absorb them and incorporate them into the

Figure 56-13 Zonation in a large, deep, temperate lake

A lake is a standing-water ecosystem surrounded by land. A large lake has littoral, limnetic, profundal, and benthic zones.

Adapted from Miller, G.T., and S.E. Spoolman, *Living in the Environment*, 17th ed. (Cengage/Brooks Cole, Belmont, CA, 2012): 182, Figure 8-16.

food web. As a result, the profundal zone tends to be both mineral rich and anaerobic (oxygen deficient), with few organisms other than anaerobic bacteria and archaea occupying it.

The **benthic zone** is the bottom layer of the lake. Decomposers, detritus feeders, and some fish live here. These organisms depend mainly on organic matter that drifts down from the upper zones.

Thermal stratification in temperate lakes The marked layering of large temperate lakes caused by light penetration is accentuated by **thermal stratification**, in which the temperature changes sharply with depth (FIG. 56-14a). Thermal stratification occurs because the summer sunlight penetrates and warms surface water, making it less dense. (Recall from Chapter 2 that the density of water is greatest at 4°C; both above and below this temperature, water is less dense.) In summer, cool (and therefore *more* dense) water remains at the lake bottom and is separated from warm (and therefore *less* dense) water above by an abrupt temperature transition called the **thermocline**. Seasonal distribution of temperature and oxygen (more oxygen dissolves in water at cooler temperatures) affects the distribution of fish in the lake.

In temperate lakes, falling temperatures in autumn cause a mixing of the lake waters called the **fall turnover** (FIG. 56-14b). As surface water cools, its density increases, and it sinks and displaces the less dense, warmer, mineral-rich water beneath. Warmer water then rises to the surface where it, in turn, cools and sinks. This process of cooling and sinking continues until the lake reaches a uniform temperature throughout.

In winter, surface water cools to below 4°C, its temperature of greatest density. Ice, which forms at 0°C, is less dense

than cold water. Thus, ice forms on the surface, and the water on the lake bottom is warmer than the ice on the surface. In spring, a **spring turnover** occurs as ice melts and surface water reaches 4°C. Surface water again sinks to the bottom, and bottom water returns to the surface. As summer arrives, thermal stratification occurs once again.

The mixing of deeper, nutrient-rich water with surface, nutrient-poor water during the fall and spring turnovers brings essential minerals to the surface and oxygenated water to the bottom. The sudden presence of large amounts of essential minerals in surface waters encourages the development of large algal and cyanobacterial populations, which may form temporary **blooms** in the fall and spring.

Increased nutrients and algal growth The presence of high levels of plant and algal nutrients such as nitrogen and phosphorus causes *enrichment*, the fertilization of a body of water. Excess amounts of these nutrients enter waterways from sewage and from fertilizer runoff from lawns and fields. The water in an enriched pond or lake is cloudy because of the vast numbers of algae and cyanobacteria that the nutrients support.

The species composition is different in enriched and unenriched lakes. For example, an unenriched lake in the northeastern United States may contain pike, sturgeon, and whitefish in the deeper, colder part of the lake where there is a higher concentration of dissolved oxygen. In contrast, the deeper, colder levels of water in enriched lakes are depleted of dissolved oxygen because of the greater amount of decomposition on the lake floor. Fishes such as pike, sturgeon, and whitefish die out,

(a)

Figure 56-14 Thermal stratification in a temperate lake

(a) Temperature varies at different depths during the summer. There is an abrupt temperature transition, the thermocline. (b) During fall and spring turnovers, a mixing of upper and lower layers of water brings oxygen to the oxygen-depleted depths of the lake and minerals to the mineral-deficient surface waters.

(b)

and fishes such as catfish and carp, which tolerate lower concentrations of dissolved oxygen, replace them.

Enrichment is reversible and has declined in North America since the 1970s because legislation limits the phosphate content of detergents and because better sewage treatment plants have been constructed. Agriculture is the leading source of water-quality impairment of U.S. surface waters today. Major causes of enrichment problems in waterways include fertilizer runoff, animal wastes, and sewage plant residues. States and communities continue to improve storm water management practices, and many have passed laws to ban phosphate fertilizers.

Freshwater wetlands are transitional between aquatic and terrestrial ecosystems Freshwater wetlands, which are usually covered by shallow water for at least part of the year, have characteristic soils and water-tolerant vegetation. They include marshes, dominated by grasslike plants, and swamps, in which woody trees or shrubs dominate (FIG. 56-15). Freshwater wetlands also include hardwood bottomland forests (lowlands along streams and rivers that are periodically flooded), prairie potholes (small, shallow ponds that formed when glacial ice melted at the end of the last Ice Age), and peat moss bogs (peat-accumulating wetlands where sphagnum moss dominates).

Wetlands are valued as a wildlife habitat for migratory waterfowl and many other bird species, beavers, otters, muskrats, and game fishes. A huge variety of microorganisms, fungi, plants, and invertebrates are also members of these ecosystems. Wetlands are holding areas for excess water when rivers flood their banks, and also for nutrient-rich runoff from surrounding land. The floodwater stored in wetlands then drains slowly back into the rivers, providing a steady flow of water throughout the year. Wetlands also serve as groundwater recharging areas. One of their most important roles is to trap and hold pollutants in the flooded soil, thereby cleansing and purifying the water. Such important environmental functions as these are known as **ecosystem services**.

Wetlands were once considered wastelands, areas to be filled in or drained so that farms, housing developments, and industrial plants could be built on them. Wetlands are also breeding places for mosquitoes and therefore were viewed as a menace to public health. The crucial ecosystem services that wetlands provide are widely recognized today, and wetlands have some legal protection. Despite this recognition of their value, agriculture, pollution, engineering (dams), and urban and suburban development continue to threaten wetlands.

Gregory J. Dimijian/Science Source

Figure 56-15 Freshwater swamp

Trees, such as bald cypress (shown), dominate freshwater swamps. In this wetland, photographed in northeastern Texas, a floating carpet of tiny aquatic plants covers the water's surface.

Figure 56-16 Salt marsh

Cordgrass (*Spartina alterniflora*) is the dominant vegetation in this salt marsh in Georgia.

Estuaries occur where fresh water and salt water meet

Where the ocean meets the land, there may be one of several kinds of ecosystems: a rocky shore, a sandy beach, an intertidal mudflat, or a tidal estuary. An **estuary** is a coastal body of water, partly surrounded by land, with access to the open ocean and a large supply of fresh water from rivers. Water levels in an estuary rise and fall with the tides, and salinity fluctuates with tidal cycles, the time of year, and precipitation. Salinity also changes gradually within the estuary, from fresh water at the river entrance to salty ocean water at the mouth of the estuary. Because estuaries undergo marked daily, seasonal, and annual variations in temperature, salinity, and other physical properties, estuarine organisms have a wide tolerance to such changes.

Estuaries are among the most fertile ecosystems in the world, often having much greater productivities than the adjacent ocean or freshwater river (see Table 55-1). This high productivity is the result of four factors: (1) the action of tides promotes a rapid circulation of nutrients, helps remove waste products, and increases oxygenation; (2) minerals, transported from land into streams and rivers emptying into the estuary, provide nutrients; (3) the high level of light that penetrates the shallow water supports photosynthesis; and (4) the presence of many plants provides an extensive photosynthetic carpet and also mechanically traps detritus, forming the basis of detritus food webs. Most commercially important fishes and shellfish spend their larval stages in estuaries among the protective tangle of decaying stems.

Temperate estuaries are usually bordered by **salt marshes**, shallow wetlands in which salt-tolerant grasses dominate (FIG. 56-16). Uninformed people have often considered salt marshes

as worthless, empty stretches of land. As a result, people have used them as dumps, severely polluting them, or filled them with dredged bottom material to form artificial land for residential and industrial development. A large part of the estuarine environment is lost in this way, along with many of its ecosystem services, such as biological habitats, sediment and pollution trapping, groundwater supply, and storm buffering (salt marshes absorb much of the energy of a storm surge and therefore prevent flood damage elsewhere).

Mangrove forests, the tropical equivalent of salt marshes, cover perhaps 70% of tropical and subtropical coastal mudflats where tides and waves fluctuate (FIG. 56-17; Chapter 54 introduction). Like salt marshes, mangrove forests provide valuable ecosystem services. Mangrove roots stabilize the sediments, preventing coastal erosion and providing a barrier against the ocean

during storms. Their interlacing roots are breeding grounds and nurseries for commercially important fish and shellfish species, such as blue crabs, shrimp, mullet, and spotted sea trout. Mangrove branches are nesting sites for many species of birds, such as pelicans, herons, egrets, and roseate spoonbills. Mangroves are under assault from coastal development, including aquaculture

Tom Stack/Alamy Stock Photo

Figure 56-17 Mangroves

Red mangroves (*Rhizophora mangle*) have stiltlike roots that support the tree. Many animals live in the complex root systems of mangrove forests. Photographed at low tide along the coast of Florida in Biscayne National Park.

Figure 56-18 Vertical zones in an ocean

The euphotic zone, the brightly lit upper region of an ocean, is inhabited by plankton and plankton-eating nekton. The bathyal zone, which receives little sunlight, does not support phytoplankton. Zooplankton and some invertebrates and fish live in the bathyal zone. The dark, cold abyssal zone is inhabited by some sponges, clams, oysters, squid, worms, and fish. Many organisms that inhabit the abyssal zone are filter feeders that depend on organic material that drifts down from the upper layers. Note that the slopes of the ocean floor are not as steep as shown; they are exaggerated to save space. Adapted from Miller, G.T., and S.E. Spoolman, *Living in the Environment*, 17th ed. (Cengage/Brooks Cole, Belmont, CA, 2012): 173, Figure 8-6.

facilities, and unsustainable logging. Some countries, such as the Philippines, Bangladesh, and Guinea-Bissau, have cut down more than two-thirds of their mangrove forests. In the United States, commercial developers, home builders, and some residents continue to sidestep conservation laws by destroying mangroves to provide waterfront properties with unobstructed views.

Marine ecosystems dominate Earth's surface

Although lakes and the ocean are comparable in many ways, they have many differences. Depths of even the deepest lakes do not approach those of the ocean, which has areas that extend more than 6 km (3.6 mi) below the sunlit surface.

Tides and currents profoundly influence the ocean. Gravitational pulls of both the sun and the moon produce two tides a day throughout most areas of the ocean, but the height of those tides varies with season, local topography, and phases of the moon (full moons and new moons cause the highest tides).

The immense, complex marine environment is subdivided into several zones based on characteristics affected by water depth and distance from shore: the narrow intertidal zone, the broad benthic (ocean floor) environment, and the vast pelagic (ocean water) environment (FIG. 56-18). The pelagic environment is, in turn, divided into two provinces: the neritic province above the continental shelves and the deep water oceanic province.

The intertidal zone is transitional between land and ocean

The **intertidal zone** is the shoreline area between low tide and high tide. Although high levels of light and nutrients, together with an abundance of oxygen, make the intertidal zone a biologically productive environment, it is also a stressful one. Predators abound in the surrounding water and in the air above. Competition is fierce for space where organisms attach to rocks and pier pilings. In the lowest, most biodiverse region of the intertidal zone, an area only exposed during the lowest lunar cycle tide, beds of algae, echinoderms, other invertebrates, and fishes dwell. If an intertidal beach is sandy, inhabitants must contend with a constantly shifting environment that threatens to engulf them and gives them scant protection against wave action. Consequently, most sand-dwelling organisms, such as mole crabs, are continual and active burrowers. Because they follow the tides up and down the beach, most do not have any notable adaptations to survive drying or exposure.

A rocky shore provides a fine anchorage for seaweeds and invertebrate animals. However, it is exposed to constant wave action when immersed during high tides and to drying and temperature changes when exposed to the air during low tides. A typical rocky-shore inhabitant has some way of sealing in moisture, perhaps by closing its shell, if it has one, plus a powerful means of anchoring itself to rocks. Mussels, for example, have horny, threadlike anchors, and barnacles have special cement glands. Rocky-shore intertidal algae (seaweeds) usually have thick, gummy polysaccharide coats, which dry out slowly when exposed, and flexible bodies not easily broken by wave action (FIG. 56-19). Some rocky-shore community inhabitants hide in burrows or crevices at low tide.

Seagrass beds, kelp forests, and coral reefs are part of the benthic environment

The **benthic environment** is

Doug Sokell/Visuals Unlimited, Inc.

Figure 56-19 Seaweeds in a rocky intertidal zone

Sea palms (*Postelsia*), which are 50 to 75 cm (20 to 30 in.) tall, are common on the rocky Pacific coast from Vancouver Island to California. The bases of these brown algae are firmly attached to the rocky substrate, enabling them to withstand heavy surf action. Photographed at low tide.

the ocean floor. It begins at the intertidal zone and is divided into zones based on distance from land, light availability, and depth. This benthic region continues along the gradually sloping *continental shelf*, which at a depth of 200 meters becomes the *continental slope* that extends out from the land as the ocean bottom.

The ocean bottom, or **abyssal zone** (abyssal plain), extends from a depth of 4000 to 6000 m (2.5 to 3.7 mi). (In Chapter 55, *Inquiring About: Life without the Sun* describes some of the unusual organisms in hydrothermal vents in the abyssal zone.) It contains deep trenches, called the **hadal zone**, which is that part of the benthic environment deeper than 6000 m with tall submarine ridges.

The benthic environment consists of sediments (mostly sand and mud) in which many marine animals, such as worms and clams, burrow. Archaea and bacteria are common in marine sediments, and living archaea and bacteria have been found in deeply buried ocean sediments at least 800 m (2600 ft) below the ocean floor at several different sites in the Pacific Ocean.

Here we describe benthic communities in shallow ocean waters: seagrass beds, kelp forests, and coral reefs. **Sea grasses** are some 60 species of flowering plants that have adapted to complete submersion in ocean water (FIG. 56-20). They are not true grasses. Sea grasses live in shallow water, to depths of 10 m (33 ft), where they receive enough light to photosynthesize efficiently. Extensive beds of sea grasses occur in calm, temperate, subtropical, and tropical waters; no sea grasses live in polar waters.

Sea grasses have a high primary productivity and are therefore ecologically important in shallow marine areas. Their roots and rhizomes stabilize the sediments, reducing surface erosion.

Sea grasses provide food and habitat for many marine organisms. In temperate waters, ducks and geese eat sea grasses; in tropical waters, manatees, green turtles, parrot fish, surgeon fish, and sea urchins eat them. These herbivores consume only about 5% of the sea grasses. The remaining 95% eventually enter the detritus food web when the sea grasses die and bacteria decompose them. In turn, a variety of animals such as mud shrimp, lug worms, and mullet consume the bacteria. Seagrass beds have been severely

Turtle grasses (*Thalassia*) have numerous invertebrates and algal epiphytes attached to their leaves. These shallow underwater meadows of marine flowering plants are ecologically important for shelter and food for many organisms. Photographed in the Red Sea, Egypt.

damaged and depleted by water pollution and by boat propellers. Fortunately, many coastal communities and environmental organizations are replanting seagrass beds and educating boaters about the importance of healthy seagrass ecosystems.

Kelps, which may reach lengths of 60 m (200 ft), are the largest brown algae (see Fig. 26-11b). Kelps are common in cooler temperate marine waters of both the Northern and Southern Hemispheres. They are especially abundant in relatively shallow waters (depths of about 25 m, or 82 ft) along rocky coastlines. Kelps are photosynthetic and are therefore the primary food producers for the kelp forest ecosystem. Kelp forests also provide habitats for many marine animals. Tube worms, sponges, sea cucumbers, clams, crabs, fishes (such as tuna), and mammals (such as sea otters) find refuge in the algal blades. Some animals eat the blades, but kelps are consumed mainly in the detritus food web. Bacteria and archaea that decompose dead kelp provide food for sponges, tunicates, worms, clams, and snails. Kelp beds support a diversity of life that almost rivals that found in coral reefs.

Coral reefs, which are built from accumulated layers of calcium carbonate (CaCO_3), are found in warm (temperature usually greater than 21°C), shallow sea water. The living portions of coral reefs grow in shallow waters where light penetrates. Many coral reefs are composed principally of red coralline algae that require light for photosynthesis. Coral animals also require light for the large number of symbiotic dinoflagellates, known as **zooxanthellae**, which live and photosynthesize in their tissues (see Fig. 54-12). Although species of coral without zooxanthellae exist, only those with zooxanthellae build reefs. Researchers have discovered some zooxanthellae that benefit from nitrogen products provided through an additional symbiotic relationship with cyanobacteria that fix nitrogen at night and early morning. Coral animal symbionts in nitrogen-depleted waters

may also benefit from this additional source of nitrogen. During the night, coral animals capture food using their stinging tentacles to paralyze small animals that drift nearby.

Coral reefs grow slowly as coral organisms build on the calcareous remains of countless organisms before them. The warm, shallow waters in which coral reefs are found are often poor in nutrients. Other factors favor high productivity, however, including the presence of symbiotic zooxanthellae, warm temperatures, and plenty of sunlight.

Coral reef ecosystems are the most diverse of all marine environments and contain hundreds or even thousands of species of fishes and invertebrates, such as giant clams, sea urchins, sea stars, sponges, brittle stars, sea fans, and shrimp (FIG. 56-21). The Great Barrier Reef, along the northeastern coast of Australia, occupies only 0.1% of the ocean's surface, but 8% of the world's fish species live there. The greatest threat to coral reef ecosystems is global warming. Massive areas of coral bleaching, caused by warmer than normal sea temperatures, were recorded from 2014 through 2016, resulting in 90% bleaching of the Great Barrier Reef and 20% death of the coral population. In some areas, such as Kenya, Sri Lanka, and the Maldives, up to 90% of coral has died.

Scientists project that more frequent episodes of coral bleaching combined with increasing ocean acidification will continue to increase coral death for the foreseeable future unless stress is reduced. Bleached corals can sometimes recover if their environment returns to more favorable living conditions. If the coral animals can regain their symbiotic zooxanthellae within weeks or a few months, they may survive.

The multitude of relationships and interactions that occur at coral reefs is comparable only to those in tropical rain forests among terrestrial ecosystems. As in the rain forest, competition is intense, particularly for light and space to grow. In both ecosystems, recycling of nutrients is also critical for their great biodiversity and high productivity to continue.

In addition to providing habitat for a wide variety of marine organisms, coral reefs are ecologically important because they protect coastlines from shoreline erosion. They also provide humans with seafood, pharmaceuticals, and income from tourism and recreation. Although coral formations are important ecosystems, they are rapidly being degraded and destroyed. According to the United Nations Environment Program, most of the world's coral reefs are threatened or at high risk. Coral reefs of Southeast Asia, which contain the most species of all coral reefs, are the most threatened of any region.

In some areas, silt washing downstream from clear-cut inland forests has smothered reefs under a layer of sediment. Some scientists hypothesize that high salinity resulting from the diversion of fresh water to supply the growing human population is killing Florida reefs. Overfishing, pollution from sewage discharge and agricultural runoff, oil spills, boat groundings, fishing with dynamite or cyanide, hurricane

Figure 56-21 Coral reef organisms

A panoramic view of a coral reef in the Indian Ocean off the coast of the Maldives. A few of the many animals that live on and around coral reefs are shown. The fish in the foreground are blue-green damselfish (*Chromis viridis*).

Figure 56-22 Fish in the open ocean

Rough triggerfish (*Canthidermis maculatus*) are tropical fish usually found in the open ocean to depths of 92 m (300 ft). Sometimes they spend time on deep rocky slopes. Photographed in the Pacific Ocean near Hawaii.

damage, disease, land reclamation, tourism, and the mining of corals for building material are also taking a heavy toll. (Coral reefs are also discussed in Chapter 31.)

The neritic province consists of shallow waters close to shore The **neritic province** is the open ocean that overlies the continental shelves, that is, the ocean floor from the shoreline to a depth of 200 m (650 ft). Organisms that live in the neritic province are floaters or swimmers (FIG. 56-22). The upper reaches of the neritic province make up the **euphotic zone**, or **epipelagic zone**, which extends from the surface to a depth of approximately 200 m (650 ft). Enough light penetrates the euphotic zone to support photosynthesis.

Large numbers of phytoplankton, particularly diatoms in cooler waters and dinoflagellates in warmer waters, produce food by photosynthesis and are thus the base of food webs. Zooplankton (including tiny crustaceans; jellyfish; comb jellies; protists such as foraminiferans; and larvae of barnacles, sea urchins, worms, and crabs) feed on phytoplankton.

Plankton-eating nekton, such as herring, sardines, squid, manta rays, and baleen whales, consume zooplankton. These, in turn, become prey for carnivorous nekton such as sharks, tuna, dolphins, and toothed whales. Nekton are thought to be mostly confined to the shallower neritic waters (less than 60 m, or 195 ft, deep) because that is where their food is. However, current research is elucidating the behavior and migration patterns of marine nekton. Many fishes appear to be wide-ranging. For example, an individual fish tagged

on one side of an ocean may be recaptured on the other side a few months later. Many biologists report that schooling and migratory behaviors may be genetically inherited, not learned behavior.

The oceanic province makes up most of the ocean The average depth of the world's ocean is 4000 m (2.4 mi). The **oceanic province** is that part of the open ocean that covers the deep-ocean basin, that is, the ocean floor at depths more than 200 m (650 ft). (See Figure 56-18 for additional information concerning ocean depth identification.) The oceanic province is the largest marine environment and contains about 75% of the ocean's water. Cold temperatures, high hydrostatic pressure, and absence of sunlight characterize the oceanic province. These environmental conditions are uniform throughout the year.

Most organisms of the oceanic province depend on **marine snow**, organic debris that drifts down into the unlit **aphotic region** from the upper, lighted regions. Organisms of this little-known realm are filter-feeders, scavengers, or predators. Many are invertebrates, some of which attain great sizes. The giant squid, for example, measures up to 18 m (59 ft) in length, including its tentacles. Fishes of the oceanic province are strikingly adapted to darkness and food scarcity. For example, the gulper eel's huge jaws enable it to swallow large prey (FIG. 56-23). (An organism that encounters food infrequently needs to eat as much as possible when it has the chance.) The lizardfish has strong pelvic fins that

Bruce H. Robison

Figure 56-23 Gulper eel from the oceanic province

The gulper eel (*Saccopharynx lavenbergi*) uses its "trap-door" jaws to swallow prey as large as itself. The tail makes up most of the length of a gulper eel's body. Gulper eels grow to 1.8 m (6 ft). Shown is a live specimen, photographed in an aquarium aboard ship after being captured at a depth of 1500 m (4921 ft) off southern California.

stabilize it in deep underwater currents. The many, long, folding teeth in its jaw and on its tongue maintain a tight hold on its prey. Many animals of the oceanic province have illuminated organs that enable them to see one another to mate or to capture food. Adapted to drifting or slow swimming, these fishes often have reduced bone and muscle mass.

Human activities are harming the ocean Because the ocean is so vast, many individuals have difficulty realizing how seriously human activities negatively impact and harm it. Development of resorts, cities, industries, transportation, and agriculture along coasts alters or destroys many coastal ecosystems, including mangrove forests, salt marshes, seagrass beds, and coral reefs. Coastal and marine ecosystems receive pollution from land, from rivers emptying into the ocean, and from atmospheric contaminants that enter the ocean via precipitation. Disease-causing viruses and bacteria from human sewage contaminate shellfish and other seafood and sometimes threaten public health. Millions of tons of trash, including plastic, fishing nets, and packaging materials, end up in coastal and marine ecosystems; some of this trash entangles, poisons, and kills marine organisms.

Less visible ocean contaminants, including fertilizers, pesticides, heavy metals, pharmaceuticals, and synthetic chemicals from agriculture and industry, continue to be detected in increasing amounts. Coastal dead zones, caused by runoff of fertilizers and burning fossil fuels, have been reported in more than 400 locations. These dead zones have severely depleted dissolved oxygen levels in bottom waters.

Offshore mining and oil drilling pollute the neritic province with oil and other contaminants. Millions of ships dump oily ballast and other wastes overboard in the neritic and oceanic provinces. Fishing is highly mechanized, and new technologies can remove every single fish in a targeted area of the ocean. Scallop dredges and shrimp trawls are dragged across the benthic environment, destroying entire communities with a single swipe. Most countries recognize the importance of the ocean to life on this planet, but few have the resources or programs to protect and manage the ocean effectively.

CHECKPOINT 56.2

- **PREDICT** Imagine that the ocean plankton suddenly disappeared. What effect would that have on the nekton and benthos?
- **CONNECT** What environmental factors are most important in determining the adaptations of organisms that live in aquatic environments?
- How do you distinguish between freshwater wetlands and estuaries? between flowing-water and standing-water ecosystems?
- **CONNECT** Compare and contrast the four main marine environments.
- **CONNECT** Which aquatic ecosystem is often compared to tropical rain forests? Why?

56.3 Ecotones

LEARNING OBJECTIVE

- 7 Define *ecotone* and describe some of its features.

We have discussed the various terrestrial biomes and aquatic ecosystems as if they were distinct and separate entities, but within landscapes, ecosystems intergrade with one another at their boundaries. The transition zone where two communities or biomes meet and intergrade is called an **ecotone** (see Chapter 54). Ecotones range in size from quite small, such as the area where an agricultural field meets a woodland or where a stream flows through a forest, to continental in scope. For example, at the border, or boundary, between tundra and boreal forest, an extensive ecotone exists that consists of tundra vegetation interspersed with small, scattered conifers. Such ecotones provide habitat diversity because they are areas where species are often living at the edge of their tolerances. Ecotones are often populated by a greater variety and density of organisms than either adjacent ecosystem (FIG. 56-24).

Ecologists who study ecotones look for adaptations that enable organisms to survive there. They also examine the relationship between species richness and ecotones and how ecotones change over time. Long-term, or longitudinal, studies of ecotones have revealed they are far from static. The ecotone boundary between desert and semiarid grassland in southern New Mexico, for example, has moved since the 1950s as the desert ecosystem has continued its expansion into the grassland.

Some researchers think ecotones may be used as indicators of global climate change because ecotone species may be more sensitive to change compared to organisms outside the transition area. To that end, researchers have demonstrated that coastal estuaries gradually move seaward or toward land in response to sea level change. Recently, scientists have experimented with salt marshes to track predicted increases in sea level. In California, U.S. ecologist Kerstin Wasson and her colleagues used a salt marsh–upland ecotone as a potential indicator of sea level rise due to climate change. The ecotone migrated rapidly in response to sea level rise, but the species composition of the plant community within the ecotone remained stable. The speed of the migration and the stability of the plant community suggested that the salt marsh–upland ecotone can be a sensitive climate change indicator.

CHECKPOINT 56.3

- What habitat feature is characteristic of an ecotone?

56.4 Biogeography

LEARNING OBJECTIVE

- 8 Define *biogeography* and briefly describe Wallace's biogeographic realms.

The study of the geographic distribution of plants and animals is called **biogeography** (see Chapter 18). Biogeographers search

Key Experiment

Does species richness vary among ecotones and their adjoining communities?

HYPOTHESIS: Ecotones have greater species richness than the communities they connect.

EXPERIMENT: Plant species were sampled for two communities in southwestern Oregon and for the ecotone between them. The communities, one with nonserpentine soil and one with serpentine soil, are defined largely by soil conditions. Nonserpentine soils (samples 1 to 10) are “normal” soils. Serpentine soils (samples 18 to 28) contain high levels of elements such as chromium, nickel, and magnesium that are toxic to many plants.

RESULTS AND CONCLUSION: The various plant species found in the two communities (yellow and blue) and in the ecotone between them (green) are shown in the graph. The ecotone had a greater richness than either adjoining community.

SOURCE: Modified from C.D. White, “Vegetation–Soil Chemistry Correlations in Serpentine Ecosystems,” Ph.D. dissertation (University of Oregon, Eugene, 1971). Reprinted with permission of Dr. Charles D. White.

Figure 56-24 Ecotones and species richness

Note that the two fescues in the figure are different species.

CONNECT Why were fireweed and knotweed samples not found in the ecotone area?

for patterns in geographic distribution and try to explain how such patterns arose, including where populations originated, how they spread, and when. Biogeographers recognize that geologic and climate changes such as mountain building, continental drift (encompassed in the theory of *plate tectonics*; see Chapter 18), which describes the continents as moving plates floating on Earth’s mantle), and periods of extensive glaciation influence the distribution of species. Biogeography is linked to evolutionary history and provides insights into how organisms may have interacted in ancient ecosystems. Studying biogeography helps us understand the continuum between ancient and modern ecosystems.

One tenet of biogeography is that each species originated only once. The particular place where such origination occurred

is known as the species’ **center of origin**. The center of origin is not a single point; rather, it is the distribution of the population when the new species originated. From its center of origin, each species spreads until a barrier of some kind halts it. Examples of barriers include an ocean, a desert, or a mountain range; unfavorable climate; and the presence of organisms that compete successfully for food or shelter.

Most plant and animal species have characteristic geographic distributions. The **range** of a particular species is that portion of Earth in which it is found. The range of some species may be a relatively small area. For example, wombats, the marsupial equivalent of groundhogs, are found only in drier parts of southeastern Australia and nearby islands. Such localized, native species are said to be **endemic**; that is, they are not found anywhere else in the world. In contrast, some species have a nearly worldwide distribution and occur on more than one continent or throughout much of the ocean. Such species are said to be **cosmopolitan**.

One of the early observations of biogeographers was that the ranges of different species do not include everywhere that they *could* survive. Central Africa has elephants, gorillas, chimpanzees, lions, antelopes, umbrella trees, and guapiruvu trees, whereas areas in South America with a similar climate have none of them. These animals and plants originated in Africa after continental drift had already separated the supercontinent Pangaea into several landmasses. The organisms could not expand their range into South America because the Atlantic Ocean was an impassable barrier. Likewise, the ocean was a barrier to South American monkeys, sloths, tapirs, balsa trees, and snakewood trees, none of which are found in Africa.

Land areas are divided into biogeographic realms

As the various continents were explored and their organisms studied, biologists observed that the world could be divided into major blocks of vegetation, such as forests, grasslands, and deserts, and that these vegetation types corresponded to specific climates. The relationship between animal distribution, geography, and climate was not deduced until 1876. At that time, Alfred Russel Wallace, who independently and concurrently discovered the same scientific theory of evolution by natural selection as Charles Darwin, divided Earth’s land areas into six major biogeographic realms: the Palearctic, Nearctic, Neotropical, Ethiopian, Oriental, and Australian (FIG. 56-25a). A major barrier separates each of the six biogeographic realms from the others and helps maintain each region’s biological distinctiveness.

Many biologists quickly embraced Wallace’s classification system, which is still considered valid today. However, human activities, such as the intentional and unintentional introduction of foreign species, are contributing to a homogenization of the biogeographic realms (see Chapter 57).

Refer to Figure 56-25a as we briefly consider some of the characteristic animals in each realm. The *Nearctic* and *Paleartic* realms are more closely related than the other regions, especially in their northern parts, where they share many animals such as wolves, hares, and caribou. This similarity may be due to a land bridge that has periodically connected Siberia and Alaska. This

(a) **Certain unique species characterize each of Wallace's six biogeographic realms.** The boundary between the Oriental and Australian realms, for example, is a deep-water gap. Wallace noted that hornbills, Sumatran tigers, orangutans, and tree shrews live west of the boundary, whereas tree kangaroos, cockatoos, birds of paradise, and cuscus live east of the boundary. Many of the Australian species are endemic; that is, they evolved in Australia and are found nowhere else. Wallace's studies of biogeography helped him develop his scientific theory of evolution by natural selection.

(b) **Updated map of biogeographic realms.** Researcher Ben Holt of the University of Copenhagen and his colleagues updated Wallace's biogeographic map by combining distributions with phylogenetic relationships. They identified 20 zoogeographic regions, which they grouped into the 11 larger realms shown here. The realms with similar colors are inhabited by similar species. Adapted from Ben G. Holt, et al., *Science* (Dec. 20, 2012).

Figure 56-25 Biogeographic realms

bridge was present until late in the Pleistocene epoch, about 10,000 years ago. Animals adapted to cold environments likely dispersed between Asia and North America along this bridge.

The *Neotropical realm* was almost completely isolated from the Nearctic realm and other landmasses for most of the past 70 million years. During this time, many marsupial species evolved. The isthmus of Panama, which formed a dry-land connection about 3 million years ago, linked North and South America and provided a route for dispersal. Only three species—the opossum, armadillo,

and porcupine—are descendants of animals that survived the northward dispersal from South America, but many species, such as the tapir and llama, are descendants of animals that survived the southward dispersal from North America. Competition from these species caused many of South America's marsupial species to go extinct.

The Sahara Desert separates the *Ethiopian realm* from other landmasses. The Ethiopian realm contains the most varied vertebrates of all six realms. Some overlap exists between the Ethiopian realm and *Oriental realm* because a land bridge with a moist climate linked Africa to Asia during the Miocene and Pliocene epochs. The Oriental realm has the fewest endemic species of all the tropical realms.

The *Australian realm* has not had a land connection with other regions for more than 85 million years. It has no native eutherian mammals, and marsupials and monotremes, including the duck-billed platypus and the spiny anteater, dominate it. Adaptive radiation of the marsupials during their long period of isolation led to species with ecological niches similar to those of eutherian mammals of other realms (see Fig. 32-28).

Advances in phylogenetic techniques have allowed researchers to update Wallace's biogeographic map by combining distributions with phylogenetic relationships for over 21,000 animal species (birds, amphibians, and mammals). British biologist Ben Holt and his colleagues identified 20 zoogeographic regions, which they grouped into 11 larger realms (FIG. 56-25b). This research expands knowledge of regional historical relationships and also allows evolutionarily unique areas of the world to be identified.

CHECKPOINT 56.4

- What is *biogeography*, and what do biogeographers do?
- Which biogeographic realm has been separated from the other biogeographic realms for the longest period? What animals characterize this biogeographic realm?

Summary: Focus on Learning Objectives

56.1 Biomes (page 1217)

1 Define *biome* and briefly describe the nine major terrestrial biomes, giving attention to the climate, soil, and characteristic plants and animals of each.

- A **biome** is a large, relatively distinct terrestrial region with characteristic climate, soil, plants, and animals.
- A frozen layer of subsoil (**permafrost**) and low-growing vegetation that is adapted to extreme cold and a short growing season characterize **tundra** (also called **arctic tundra**), the northernmost biome. **Alpine tundra**, at higher elevations above the tree line, and **Antarctic tundra** of the Southern Hemisphere are also included in the tundra biome classification.
- Conifers—which are adapted to cold winters, a short growing season, and acidic, mineral-poor soil—dominate the **boreal forest**, or **taiga**.
- Large conifers dominate **temperate rain forest**, which receives high precipitation.
- **Temperate deciduous forest** occurs where precipitation is relatively high and soils are rich in organic matter. Broad-leaf trees that lose their leaves seasonally dominate temperate deciduous forest.
- **Temperate grassland** typically has a deep, mineral-rich soil and has moderate but uncertain precipitation.
- Thickets of small-leaf evergreen shrubs and trees and a climate of wet, mild winters and dry summers characterize **chaparral**.
- **Desert**, found in both temperate (cold deserts) and subtropical or tropical regions (warm deserts) with low levels of precipitation, is inhabited by organisms with specialized water-conserving adaptations.
- Tropical grassland, called **savanna**, has widely scattered trees interspersed with grassy areas. Savanna occurs in tropical areas with low or seasonal rainfall. Mineral-poor soil and high rainfall that is evenly distributed throughout the year characterize **tropical rain forest**. Tropical rain forest has high species richness and high productivity. A rain forest has several stories of vegetation: emergent layer, canopy, understory, shrub layer, and ground layer.

2 Describe at least one human effect on each of the biomes discussed.

- Oil exploration and military exercises result in long-lasting damage to tundra. Human-caused global warming is accelerating permafrost melting. Clear-cut logging destroys boreal and temperate rain forests. Temperate deciduous forests are removed for logging, farms and tree plantations, and land development.
- Human population growth and its accompanying agricultural and industrial expansion threaten most of the world's tropical rain forests.
- Farmland has replaced most temperate grasslands; savannas are increasingly converted to rangeland for cattle. Development of hilly chaparral results in mud slides and costly fires. Land development in deserts reduces wildlife habitat.

56.2 Aquatic Ecosystems (page 1226)

3 Explain the important environmental factors that affect aquatic ecosystems.

- In aquatic ecosystems, important environmental factors include **salinity** (concentration of dissolved salts), amount of dissolved oxygen, availability of light, levels of essential minerals, water depth, temperature, pH, and presence or absence of waves and currents.

4 Distinguish among plankton, nekton, and benthos.

- Aquatic life is ecologically divided into **plankton** (free-floating organisms), **nekton** (strongly swimming organisms), and **benthos** (bottom-dwelling organisms).
- **Phytoplankton** includes photosynthetic algae and cyanobacteria; **zooplankton** includes protozoa, tiny crustaceans, and the larval stages of many animals.

5 Briefly describe the various freshwater, estuarine, and marine ecosystems, giving attention to the environmental characteristics and representative organisms of each.

- Freshwater ecosystems include flowing-water ecosystems, standing-water ecosystems, and freshwater wetlands. In

flowing-water ecosystems, the water flows in a current. Flowing-water ecosystems have few phytoplankton and depend on detritus from the land for much of their energy.

- Large **standing-water ecosystems** (freshwater lakes) are divided into zones on the basis of water depth. The marginal **littoral zone** contains emergent vegetation and algae. The **limnetic zone**, open water away from the shore that extends as far down as sunlight penetrates, contains phytoplankton, zooplankton, and larger fishes. The deep, dark **profundal zone** holds little life other than bacterial decomposers.
- **Freshwater wetlands** are transitional between freshwater and terrestrial ecosystems. They are usually covered at least part of the year by shallow water and have characteristic soils and vegetation. Freshwater wetlands perform many valuable **ecosystem services**.
- An **estuary** is a coastal body of water, partly surrounded by land, with access to both the ocean and a large supply of fresh water from rivers. Salinity fluctuates with tidal cycles, the time of year, and precipitation. Temperate estuaries usually contain **salt marshes**, whereas **mangrove forests** dominate tropical coastlines.
- Four important marine environments are the intertidal zone, the benthic environment, the neritic province, and the oceanic province. The **intertidal zone** is the shoreline area between low tide and high tide. Organisms of the intertidal zone have adaptations to resist wave action and being exposed to air during low tide.
- The **benthic environment** is the ocean floor. **Sea grasses, kelps, and coral reefs** are important benthic communities in shallow ocean waters.
- The **neritic province** is open ocean from the shoreline to a depth of 200 m. Organisms that live in the neritic province are all floaters or swimmers. The **euphotic zone** is the upper part of the neritic province, where enough light penetrates to support photosynthesis. Phytoplankton are the base of the food web in the euphotic zone.
- The **oceanic province** is that part of the open ocean that is deeper than 200 m. Its uniform environment is one of darkness, cold temperature, and high pressure. Animal inhabitants of the oceanic province are either predators or scavengers that subsist on **marine snow**, detritus that drifts down from other areas of the ocean.

6 Describe at least one human effect on each of the aquatic ecosystems discussed.

- Water pollution and dams adversely affect flowing-water ecosystems. Increased nutrients, supplied by human activities, stimulate algal growth, resulting in enriched ponds and lakes.
- Agriculture, pollution, and land development threaten wetlands and estuaries. Pollution, coastal development, offshore mining and oil drilling, and overfishing threaten marine ecosystems.
- Coral reefs are stressed, causing coral bleaching and death, from increasing water temperatures and acidification produced by human-caused climate change.

56.3 Ecotones (page 1235)

7 Define ecotone and describe some of its features.

- An **ecotone** is the transition zone where two communities or biomes meet and intergrade. Ecotones provide habitat diversity because they are areas where species are often living at the edge of their tolerances. Ecotones are often populated by a greater variety and density of organisms than either adjacent ecosystem.

56.4 Biogeography (page 1235)

8 Define biogeography and briefly describe Wallace's biogeographic realms.

- **Biogeography** is the study of the geographic distribution of plants and animals, including where populations came from, how they got there, and when. Each species originated only once, at its **center of origin**. From its center of origin, each species spreads until a physical, environmental, or biological barrier halts it. The **range** of a particular species is that portion of Earth in which it is found.
- Alfred Russel Wallace divided Earth's land areas into six major biogeographic realms: the Palearctic, Nearctic, Neotropical, Ethiopian, Oriental, and Australian. Each realm is biologically distinct because a mountain range, desert, deep water, or other barrier separates it from the others.
- Phylogenetic techniques have allowed researchers to update Wallace's biogeographic map by combining species distributions with phylogenetic relationships. Scientists identified 20 zoogeographic regions, which they grouped into 11 larger realms.

Test Your Understanding

Know and Comprehend

1. The northernmost biome, known as _____, typically has little precipitation, a short growing season, and permafrost. (a) chaparral (b) boreal forest (c) tundra (d) northern deciduous forest (e) savanna
2. Forests of the northeastern and middle Atlantic United States, which have broad-leaf hardwood trees that lose their foliage annually, are called (a) temperate deciduous forests (b) tropical dry forests (c) boreal forests (d) temperate rain forests (e) tropical rain forests
3. The deepest, richest soil in the world occurs in (a) temperate rain forest (b) tropical rain forest (c) savanna (d) temperate grassland (e) chaparral
4. This biome, with its thicket of evergreen shrubs and small trees, is found in areas with Mediterranean climates. (a) temperate rain forest (b) tropical rain forest (c) savanna (d) temperate grassland (e) chaparral
5. This biome is a tropical grassland interspersed with widely spaced trees. (a) temperate rain forest (b) tropical rain forest (c) savanna (d) temperate grassland (e) chaparral
6. This biome has the greatest species richness. (a) temperate rain forest (b) tropical rain forest (c) savanna (d) temperate grassland (e) chaparral
7. Organisms in aquatic environments fall into three categories: free-floating _____, strongly swimming _____, and bottom-dwelling _____.

- (a) nekton; benthos; plankton (b) nekton; plankton; benthos
(c) plankton; benthos; nekton (d) plankton; nekton; benthos
(e) benthos; nekton; plankton
8. Emergent vegetation grows in the _____ zone of freshwater lakes. (a) littoral (b) limnetic (c) profundal (d) neritic (e) intertidal
9. The _____ is open ocean from the shoreline to a depth of 200 m. (a) benthic environment (b) intertidal zone (c) neritic province (d) oceanic province (e) aphotic region
10. The transition zone where two ecosystems or biomes meet and intergrade is called (a) a biosphere (b) an aphotic region (c) a thermocline (d) a biogeographic realm (e) an ecotone
11. Which biogeographic realm has been separated from the other landmasses for more than 85 million years? (a) Ethiopian (b) Palearctic (c) Nearctic (d) Oriental (e) Australian

Apply and Analyze

12. **INTERPRET DATA** Develop a hypothesis to explain why animals adapted to the desert are usually small. How would you test your hypothesis?
13. **INTERPRET DATA** Examine Figure 56-1. What is the lowest average annual precipitation characteristic of tropical rain forests? the highest? What is the range of average temperature in tropical rain forests?
14. **INTERPRET DATA** Examine Figure 56-24. How many of the sampled species are found in the nonserpentine soil? in the serpentine soil? in the ecotone? What generalization about ecotones do these data support?

Evaluate and Synthesize

15. **PREDICT** What would happen to the organisms in a river with a fast current if a dam were built? Would there be any differences in habitat if the dam were upstream or downstream of the organisms in question? Explain your answers.
16. **EVOLUTION LINK** When a black-tailed prairie dog or other small animal dies, other prairie dogs bury it. Develop a hypothesis to explain how this behavior may be adaptive. How would you test this hypothesis?

57 Biological Diversity and Conservation Biology

The Cross River gorilla, *Gorilla gorilla diehli*, was discovered early in the 20th century (see photograph). It was eventually identified as a fourth subspecies of gorilla and second member of the western lowland gorilla family. This rarest of all the great apes lives in small groups in highland forests of Nigeria and western Cameroon. Cross River gorillas, listed as critically endangered (estimated population 200 to 300), are rapidly facing extinction due to habitat loss caused by human destruction. Local people have cut down, or destroyed, much of the forests for lumber, cattle grazing, and agriculture. The gorillas have been hunted and poached for bush meat.

The World Wildlife Federation (WWF) reports that these gorillas also face the risk of inbreeding and loss of genetic diversity due to their small population size and the low rate of genetic exchange between the different subpopulations. The WWF has partnered with the Wildlife Conservation Society and the governments of Nigeria and Cameroon to protect the fragile Cross River gorilla groups by establishing a forest sanctuary, enforcing laws, and supporting government management of the Campo Ma'an National Park in Cameroon and the surrounding buffer zone. Both Cameroon and Nigeria are working with local people to educate about sustainable use of forest resources and to promote alternative sources of income, such as tourism. Plans for the survival of the Cross River gorillas will focus on developing protected corridors of forest habitat that will allow safe movement of gorillas between different groups to increase genetic diversity.

Humans are very closely related to gorillas, both in our evolutionary development and genetically. In 2012, researchers reported in *Nature* that when the western lowland gorilla genome was sequenced, they found that 15% of the human genome was more closely related to gorillas than to chimpanzees. Scientists also confirmed that the gorilla is about 98% genetically identical to us.

KEY CONCEPTS

- 57.1** Never before in Earth's history has biodiversity been threatened with mass extinction in such a compressed time period by one species: *Homo sapiens*.
- 57.2** Conservation biology is a multidisciplinary science that studies human effects on biodiversity and devises practical solutions to address these effects.
- 57.3** Globally, removal of large expanses of forest for timber, agriculture, and other uses is contributing to the loss of biological diversity and valuable ecosystem services.
- 57.4** Scientists continue to study global climate change, which is adversely affecting biodiversity, human health, and agriculture.

PHOTO: Cross River gorilla (*Gorilla gorilla diehli*). Will this critically endangered species survive? PureStock/Alamy Stock Photo

Further, we share some rapidly evolving genes with gorillas, which may facilitate medical research of such ailments as heart disease and dementia. The study increases our understanding of human evolution and, according to the researchers, “connects us to a time when our existence was more tenuous, and in doing so, highlights the importance of protecting and conserving these remarkable species.”

The Cross River gorilla decline underscores how humans have negatively affected biological diversity. For example, according to the International Union for the Conservation of Nature (IUCN), which monitors the status of Earth’s biological diversity, one-fourth of the world’s mammals are at risk of extinction. Our recognition of this serious situation and our efforts to address the damage we have caused may well be what ultimately ensures our own human survival.

In this chapter we focus on declining biological diversity and conservation biology. We discuss deforestation and climate change, two major environmental issues that negatively affect biological diversity.

57.1 The Biodiversity Crisis

LEARNING OBJECTIVES

- 1 Identify various levels of biodiversity: genetic diversity, species richness, and ecosystem diversity.
- 2 Distinguish among threatened species, endangered species, and extinct species.
- 3 Discuss at least four causes of declining biological diversity and identify the most important causes.

The human species (*Homo sapiens*) has been present on Earth for about 300,000 years (see Chapter 22), a brief span of time compared with the age of our planet, some 4.6 billion years. Despite our relatively short tenure on Earth, our biological effect on other species is unparalleled. Our numbers have increased dramatically—the human population reached 7.5 billion in 2017—and we have expanded our biological range, moving into almost every habitat on Earth.

The term “Anthropocene” was suggested in 2000 by Dutch Nobel Prize-winning scientist Paul Crutzen to describe the geological epoch in which we live. The Anthropocene, or “Age of Humans,” is defined by the transformations humans have effected. For example, our planet now has strata that include plastics, concrete, elemental aluminum and other metals, and human-produced radioactive isotopes. The concept of advancing from the Holocene to the Anthropocene is being debated by an international group of scientists. Will scientists recognize the concept? If so, how will it be described?

Many scientists think that the Anthropocene began around 1945 at the end of World War II. Other researchers debate that the coal-burning Industrial Age, hundreds of years earlier, defines the beginning of the epoch. Most scientists agree, however, that human transformations to Earth are more than only geological in nature. They recognize that we humans have become the “dominant ecological force” on Earth (as described in this chapter, Chapter 56, and throughout this

book). The idea of an Anthropocene epoch marks a change in functioning (for better and for worse) of all Earth’s systems and organisms.

Wherever we have lived, we have altered the environment and shaped it to meet our needs. In only a few generations, we have transformed the face of Earth, placed a great strain on Earth’s resources and resilience, and profoundly affected other species. As a result of these changes, we must all be concerned about **environmental sustainability** (or simply, *sustainability*), the ability to meet humanity’s current needs without compromising the ability of future generations to meet their needs. The effect of humans on the environment merits special study in biology, not merely because we ourselves are humans but because our impact on the rest of the biosphere is so extensive.

Extinction, the death of a species, occurs when the last individual member of a species dies. (We introduced the important concept of extinction in Chapter 20.) Although extinction is a natural biological process, human activities have greatly accelerated it (**FIG. 57-1**). According to the 2005 Millennium Ecosystem Assessment report, extinction is happening about 1000 times more rapidly than the normal background rate of extinction. (More recent estimates increase this number to 10,000 times.) Researchers estimate that dozens of species become extinct each day. Many of these species have never even been identified. The burgeoning human population has forced us to spread to almost all areas of Earth. Whenever humans invade an area, the habitats of many plants and animals are disrupted or destroyed, which can contribute to their extinction.

Recent examples of human-caused extinction in the early 21st century include the Javan tiger, Western black rhinoceros, Pyrenean ibex, and Formosan clouded leopard. Like the famed dodo and carrier pigeon of previous centuries, these animals were hunted or poached until the species could no longer survive. Many hundreds of animal species no longer have the viable populations needed to survive due to habitat loss, pollution, hunting, and global warming. In the United States alone, tens of thousands of species of plants are listed as endangered or threatened due to overgrazing, habitat loss from land development, and climate change.

Biological diversity, also called **biodiversity**, is the variation among organisms (**FIG. 57-2**). Biological diversity includes much more than simply **species richness**, the number of species of archaea, bacteria, protists, plants, fungi, and animals. Biological diversity occurs at all levels of ecological organization, from populations to ecosystems. It takes into account **genetic diversity**, the genetic variety within a species, both among individuals within a given population and among geographically separate populations. (An individual species may have hundreds of genetically distinct populations.) Biological diversity also includes **ecosystem diversity**, the variety of ecosystems found on Earth: the forests, prairies, deserts, lakes, coastal estuaries, coral reefs, and other ecosystems.

Biologists must consider all three levels of biological diversity—species richness, genetic diversity, and ecosystem diversity—as they address the human impact on biodiversity. For example, the disappearance of populations (i.e., a decline in genetic diversity) indicates an increased risk that a species will become extinct

These animals became extinct largely as a result of human activities, such as destruction of their habitats and hunting.

(a decline in species richness). Biologists perform detailed analyses to quantify how large a population must be to ensure a given species' long-term survival. The smallest population that has a high chance of enduring into the future is known as the **minimum viable population (MVP)**.

Biological diversity is currently decreasing at an unprecedented rate (see *Inquiring About: Declining Amphibian Populations*). For example, the IUCN Red List, which is based on 25 years of data collection and analysis around the world, lists about 79,800 species of which more than 23,000 are threatened with extinction, including more than 40% of amphibians, 25% of mammals, and 34% of conifers. Because Red Lists continue to change as more organisms are identified, it is difficult to know and communicate the true scale of the biodiversity crisis.

We may have entered the greatest period of mass extinction in Earth's history, but the current situation differs from previous periods of mass extinction in several respects. (See Chapter 21 to review the discussion of previous mass extinctions.) First, its cause is directly attributable to human activities. Second, it is occurring in a tremendously compressed period (just a few decades as opposed to hundreds of thousands of years), much faster than rates of speciation (or replacement). Perhaps even more sobering, larger numbers of plant species are becoming extinct today than in previous mass extinctions. Because plants are the base of terrestrial food webs, extinction of animals that depend on plants is not far behind. It is crucial that we determine how the loss of biodiversity affects the stability and functioning of ecosystems, which make up our life-support system.

The legal definition of an **endangered species**, as stipulated by the U.S. Endangered Species Act, is a species in imminent danger of extinction throughout all or a significant part of its range. (The area in which a particular species is found is its **range**.) Unless humans intervene, an endangered species will probably become extinct.

When extinction is less imminent but the population of a particular species is quite small, the species is classified as threatened. The legal definition of a **threatened species** is a species likely to become endangered in the foreseeable future, throughout all or a significant part of its range.

Endangered and threatened species represent a decline in biological diversity because as their numbers decrease, their genetic diversity is severely diminished. Endangered and threatened species are at greater risk of extinction than species with greater genetic variability because long-term survival and evolution depend on genetic diversity (see the section on genetic drift in Chapter 19).

Endangered species have certain characteristics in common

Many threatened and endangered species share certain characteristics that may make them more vulnerable to extinction. Some of these characteristics include having an extremely small (localized) range, requiring a large territory, living on islands, having a low reproductive success, needing specialized breeding areas, and possessing specialized feeding habits.

Key Point

Genetic diversity affects a population's ability to thrive, which in turn affects species richness within an ecosystem. Ultimately, species richness helps determine ecosystem diversity across a large area.

(a) Genetic diversity in an American oystercatcher population.

(b) Species richness in an East Coast sandy shore ecosystem.

(c) Ecosystem diversity across an entire region (ocean and shore).

Figure 57-2 Levels of biodiversity

Conservation at all three ecological levels must occur to protect biological diversity. In (a), the single unduplicated chromosome below each oystercatcher represents the genetic variation among individuals within a population.

Many endangered species have a small natural range, which makes them particularly prone to extinction if their habitat is altered. The Tiburon mariposa lily, for example, is found nowhere in nature except on a single hilltop near San Francisco. Wildfire or development of that hilltop would almost certainly cause the extinction of this species.

Species that need extremely large territories may be threatened with extinction when all or part of their territory is modified by human activity. The California condor, for example, is a scavenger bird that lives off carrion and requires hundreds of square kilometers of undisturbed territory to find adequate food. The condor is slowly recovering from the brink of extinction. From 1987 to 1992, it existed only in zoos and was not found in nature. A program to reintroduce zoo-bred California condors into the wild began in 1992. Currently, there are more than 435 condors, with nearly two-thirds of them living in the wild in California, Arizona, Utah, and Baja, Mexico. The condors have not yet become a self-sustaining population that replaces its numbers without captive breeding. Establishing a self-sustaining population in the wild has been slow due mainly to bird deaths from lead poisoning. Condors feed on animal carcasses containing lead shot and die when internal accumulation of lead causes digestive system paralysis. Fortunately, legislation and public awareness now supports switching to non-lead shot.

Many **endemic** island species are endangered. (*Endemic* means that they are local species not found anywhere else in the world.) These species often have small populations that cannot be replaced by immigration if their numbers decline. Because they evolved in isolation from competitors, predators, and disease organisms, island species have few defenses when such organisms are introduced, usually by humans. It is not surprising that of the nearly 200 bird species that have become extinct in the past few centuries, over 75% lived on islands.

For a species to survive, its members must be present within their range in large enough numbers for males and females to mate. The minimum viable population that ensures reproductive success varies from one type of organism to another. For all species, when the population size falls below the MVP, the population goes into a decline and becomes susceptible to extinction.

Endangered species often have low reproductive rates. The female blue whale produces a single calf every other year, whereas no more than 6% of swamp pinks, an endangered species of small flowering plant, produce flowers in a given year (FIG. 57-3). Some endangered species breed only in specialized areas; for example, the green sea turtle lays its eggs on just a few beaches.

Highly specialized feeding habits endanger a species. In nature, the giant panda eats only bamboo. Periodically, all the bamboo plants in a given area flower and die together; when that occurs, panda populations face starvation. Like many other endangered species, giant pandas are also endangered because their habitat has been fragmented by logging and

PREDICT What might happen to this oystercatcher population if another population of oystercatchers were to migrate to the area and compete for food and space?

Inquiring About

Declining Amphibian Populations

What is happening to our amphibian populations? Since the 1970s, many of the world's frog populations have dwindled or disappeared. According to the IUCN Global Amphibian Assessment, as many as 168 amphibian species may have disappeared since 1980 and are presumed extinct. About one-third of all amphibian species are in decline, and more than 40% are at risk of becoming extinct by 2060 if they are not taken into captivity.

The declines are not limited to areas with obvious habitat destruction (such as drainage of wetlands where frogs live), degradation from pollutants, or overharvesting. Some remote, pristine locations also show dramatic declines in amphibians. Researchers have reported evidence that pollutants, infectious diseases, and climate change are all factors in these declines.

Agricultural chemicals are implicated in amphibian declines in California's Sierra Nevadas. Frog populations on the eastern slopes are relatively healthy, but about eight species are declining on the western slopes, where prevailing winds carry residues of 15 different pesticides from the Central Valley's agricultural region. Agricultural chemicals are also implicated in amphibian declines on the eastern shore of Maryland and in Ontario, Canada. Researchers at the University of South Florida found that atrazine (an herbicide) combined with phosphate fertilizer increased trematode (a parasitic flatworm) infection and suppressed the immune system, making it difficult

for amphibians to fight parasitic infections. Subsequent research exposing trematode-infected frogs to several commonly used agrochemicals supports previous experiments.

Infectious diseases are strongly implicated in some of the declines. In 1998, a chytrid (fungus) was first connected to amphibian declines. Climate change may be exacerbating chytrid-induced amphibian deaths, and this factor continues to be investigated. At certain altitudes and temperatures, the chytrid has infected and killed 85% of the amphibians.

The discovery of amphibians with deformities adds another layer of complexity to the amphibian crisis (see photograph). Frogs with extra legs, extra toes, eyes located on the shoulder or back, deformed jaws, missing legs, missing toes, or missing eyes usually die before they reproduce. Predators easily catch frogs with extra or missing legs. Deformed amphibians have been reported on four continents and in almost all states in the United States.

Biologists have investigated many possible

causes of amphibian deformities during development, and no single factor explains the deformities found in all locations. Several pesticides affect normal development in frog embryos. Also, infecting tadpoles with a trematode causes the adults that develop from the tadpoles to exhibit limb deformities. Multiple human-caused environmental stressors, such as habitat loss and pollution, in combination with disease, may interact synergistically with one another to cause deformities and reduced immunity.

Suzanne L. and Joseph T. Collins/Science Source

Frog deformity. Pollution and parasites are implicated in developmental abnormalities in amphibians, such as this Plains leopard frog (*Rana blairi*) with deformed hind limbs in Kansas.

agriculture; there are few intact habitats where they can survive. China's 1870 wild giant pandas live in 20 isolated habitats that represent a small fraction of their historic range.

Human activities contribute to declining biological diversity

Species become endangered and extinct for a variety of reasons, including the destruction or modification of habitats (i.e., land use change) and the production of pollution, including the greenhouse gases that cause climate change. Humans also upset the delicate balance of organisms in a given area by introducing invasive species, which compete with or are pathogenic to native organisms. Overexploitation through overfishing, hunting, and poaching is also a factor. **FIGURE 57-4** shows the interactions between these direct causes of declining biological diversity and indirect human factors such as human population increase.

To save species, we must protect their habitats Most species facing extinction today are endangered by destruction, fragmentation, or degradation of natural habitats. Building roads, parking lots, bridges, and buildings; clearing forests to grow crops or graze domestic animals; and logging forests for

timber all take their toll on natural habitats. Draining marshes converts aquatic habitats to terrestrial ones, whereas building dams and canals floods terrestrial habitats (**FIG. 57-5**). Because most organisms require a particular type of environment, habitat destruction reduces their biological range and ability to survive.

Humans often leave small, isolated patches of natural landscape that roads, fences, fields, and buildings completely surround. In ecological terms, *island* refers not only to any landmass surrounded by water, but also to any isolated habitat surrounded by an expanse of unsuitable territory. Accordingly, a small patch of forest surrounded by agricultural and suburban lands is considered an island.

Habitat fragmentation, the breakup of large areas of habitat into small, isolated segments (i.e., islands), is a major threat to the long-term survival of many populations and species (**FIG. 57-6**). Species from the surrounding “developed” landscape may intrude into the isolated habitat (the *edge effect*, discussed in Chapter 54), whereas rare and wide-ranging species that require a large patch of undisturbed habitat may disappear altogether. Habitat fragmentation encourages the spread of *invasive species*, disease organisms, and other “weedy” species and makes it difficult for organisms to migrate. Generally, habitat fragments support only a fraction of the species found in the original, unaltered environment. However,

Jeffrey Lepore/Science Source

Figure 57-3 The swamp pink, an endangered species

The swamp pink (*Helonias bullata*) lives in boggy areas of the eastern United States. Photographed in Killens Pond State Park, Delaware.

much remains to be learned about precisely how habitat fragmentation affects specific populations, species, and ecosystems.

Human activities that produce acid precipitation and other forms of pollution indirectly modify habitats left undisturbed and in their natural state. Acid precipitation, also called acid rain or industrial precipitation, has contributed to the decline of large stands of forest trees and to the biological death of many freshwater lakes in, for example, the Adirondack Mountains and Nova Scotia. Acid rain is especially problematic in much of Eastern Europe and around industrial regions of China. Other types of pollutants, such as chemicals from industry and agriculture, organic pollutants from sewage, acid wastes seeping from mines, thermal pollution from the heated wastewater of industrial plants, and radioactive contamination, also adversely affect organisms.

To save native species, we must control intrusions of invasive species Biotic pollution, the introduction of a foreign species into an area where it is not native, often upsets the balance among the organisms living in that area and interferes with the ecosystem's normal functioning. Unlike other forms of pollution, which may be cleaned up, biotic pollution is usually permanent. The foreign species may prey on native species or compete with them for food or habitat. If the foreign species causes economic or environmental harm, it is known as an **invasive species**. Generally, a foreign competitor or predator harms local organisms more than do native competitors or predators. Most invasive species lack natural agents (such as parasites, predators, and competitors) that would otherwise

Because direct and indirect causes of decreased biodiversity interact in complex ways, declining biodiversity is addressed from a systems biology perspective rather than from a more-specific approach.

Figure 57-4 Causes of declining biological diversity

Indirect causes (*blue*) of decreasing biodiversity interact with and amplify the effects of one another and of direct causes (*green*). Note that each of these causes can be traced to human activities.

CONNECT Give an example of how an indirect effect could positively change a direct effect.

Frans Lanting/MINT Images/Science Source

Figure 57-5 Habitat destruction

This tiny island lies in the Panama Canal. It was once a hilltop in a forest that was flooded when the canal was built.

Key Experiment

How does habitat fragmentation affect predation of juvenile bay scallops in a marine environment?

HYPOTHESIS: Predation on juvenile bay scallops is greater in patchy areas of sea grass than in undisturbed (continuous) seagrass meadows.

EXPERIMENT: Predation rates on juvenile bay scallops were measured over a four-week period in three seagrass environments: continuous, patchy, and very patchy.

RESULTS AND CONCLUSION: The lowest rate of predation (52%) occurred in the continuous seagrass meadow, and the highest predation rate (92%) occurred in the very patchy environment. The patchy (fragmented) areas provided the predators with easier access to the young scallops than did the continuous area. It was also more difficult for the predators to intrude from surrounding areas into the continuous seagrass meadow.

SOURCE: Irlandi, E.A., W.G. Ambrose, and B.A. Orlando, "Landscape Ecology and the Marine Environment: How Spatial Configuration of Seagrass Habitat Influences Growth and Survival of the Bay Scallop," *Oikos*, Vol. 72 (1995).

Figure 57-6 Effects of habitat fragmentation in a shallow marine environment

PREDICT What is likely to happen to bay scallop populations if seagrass environments continue to deteriorate and become more fragmented?

control them. Also, without a shared evolutionary history, most native species typically are less equipped to cope with invasive species. Although foreign species sometimes spread into new areas on their own, humans are usually responsible for such introductions, either knowingly or accidentally.

One of North America's greatest biological threats is the zebra mussel, a native of the Caspian Sea. It was introduced by a Eurasian ship that flushed ballast water into the Great Lakes in 1988. Since then, the tiny freshwater mussel, which clusters in extraordinary densities, has massed on hulls of boats, piers, buoys, water intake systems, and, most damaging of all, on native clam and mussel shells. The zebra mussel's large appetite for algae, phytoplankton, and zooplankton is also cutting into the food supply of native fishes, mussels, and clams, threatening their survival.

The zebra mussel is currently found in 29 states, parts of Canada, and throughout the Mississippi River and its tributary rivers and inland lakes. The United States spends an estimated \$10 billion each year to control the spread of the zebra mussel and to repair damage such as clogged pipes (**FIG. 57-7**).

Islands are particularly susceptible to the introduction of invasive species. In Hawaii the introduction of sheep has imperiled both the mamane tree (because the sheep eat it) and a species of honeycreeper, an endemic bird that relies on the tree for food. Hawaii's plants evolved in the absence of herbivorous mammals and therefore have no defenses against introduced sheep, pigs, goats, and deer.

Other human activities affect biodiversity directly or indirectly Sometimes species become endangered or extinct as a result of deliberate efforts to eradicate or control their numbers, often because they prey on game animals or livestock. In the past, ranchers, hunters, and government agents decimated populations of large predators such as the wolf, mountain lion, and grizzly bear. Some animals are killed because their lifestyles cause problems for humans. The Carolina parakeet, a beautiful green, red, and yellow bird endemic to the southeastern United States, was extinct by 1920, due to extermination by farmers, deforestation, and hunting the bird for its colorful feathers.

Unregulated hunting, or overhunting, has caused the extinction of certain species in the past but is now strictly controlled in most countries. The passenger pigeon was one of the most common birds in North America in the early 1800s, but a century of overhunting resulted in its extinction in the early 1900s.

Illegal commercial hunting, or *poaching*, endangers larger animals such as the tiger, cheetah, and snow leopard, whose beautiful

Illinois Department of Natural Resources

Figure 57-7 Zebra mussels clog a pipe

Thumbnail-sized zebra mussels (*Dreissena polymorpha*) have caused billions of dollars in damage in addition to displacing native clams and mussels.

furs are quite valuable. Rhinoceroses are slaughtered for their horns (used for ceremonial dagger handles in the Middle East and for purported medicinal purposes in Asian medicine). Elephants are poached for their ivory tusks. Bears are killed for their gallbladders (which Asian doctors use to treat ailments ranging from indigestion to hemorrhoids). Bushmeat—meat from wild animals, including rare primates, elephants, anteaters, and great apes—is sold to urban restaurants. Although laws protect these animals, demand for their products on the black market has promoted illegal hunting, particularly in impoverished countries where a sale of contraband products can support a family for months.

Shark finning, removing a shark's fin and throwing the animal back in the ocean to die, has caused a third of the world's shark species to become endangered, according to the International Union for the Conservation of Nature (IUCN). The fins are sold to China and other Asian countries for shark fin soup and medicinal purposes. One million sharks were reportedly harvested in 2012. Sharks play an important role in maintaining ecosystems and many are keystone species. Many countries have passed laws banning any trading in shark fins, or restricting harvest of depleted species. Phylogenetic DNA testing, developed to identify illegal catches of banned species using samples of confiscated fins and shark soup, has met with some success. Unfortunately, world shark harvests seem to be increasing, despite bans on finning, as people are consuming more shark meat. In most countries that have banned finning, harvesting the entire shark is not illegal.

Commercial harvest is the collection of live organisms from nature. Most commercially harvested organisms end up in zoos, aquaria, biomedical research labs, circuses, and pet stores. For example, several million birds are commercially harvested each year for the pet trade, but many die in transit, and many more die from improper treatment in their owners' homes. At least 40 parrot species are now threatened or endangered, in part because of commercial harvest. Although it is illegal to capture endangered animals from the wild, a thriving black market exists, mainly because collectors in the United States, Europe, and Japan pay large sums for rare tropical birds (FIG. 57-8).

Figure 57-8 Illegal commercial harvesting

These caged orange-fronted conures (*Eupsittula canicularis*), native to Mexico and Central America, are part of the illegal animal trade.

Commercial harvest also threatens plants. Many unique or rare plants have been so extensively collected from the wild that they are now classified as endangered. Included are certain carnivorous plants, wildflower bulbs, cacti, and orchids. In contrast, carefully monitored and regulated commercial use of animal and plant resources creates an economic incentive to ensure that these resources do not disappear.

CHECKPOINT 57.1

- What are the three levels of biological diversity?
- **PREDICT** Which organism is more likely to become extinct: an endangered species or a threatened species? Explain your answer.
- **CONNECT** How does habitat fragmentation contribute to declining biological diversity?
- **CONNECT** How do invasive species contribute to the biodiversity crisis?

57.2 Conservation Biology

LEARNING OBJECTIVES

- 4 Define *conservation biology* and compare in situ and ex situ conservation measures.
- 5 Describe the benefits and shortcomings of the U.S. Endangered Species Act and the Convention on International Trade in Endangered Species of Wild Flora and Fauna.

Conservation biology is the scientific study of how humans impact organisms and of the development of strategies to protect biological diversity. Conservation biologists develop models, design experiments, and perform fieldwork to address a wide range of questions. For example, what are the processes that influence a decline in biological diversity? How do we protect and restore populations of endangered species? If we are to preserve entire ecosystems and landscapes, which ones are the most important to save?

Conservation biologists have determined that a single large area of habitat capable of supporting several populations is more effective at safeguarding an endangered species than several habitat fragments, each capable of supporting a single population. Also, a large area of habitat typically supports greater species richness than several habitat fragments.

Conservation is more successful when habitat areas for a given species are in close proximity rather than far apart. If an area of habitat is isolated from other areas, individuals may not effectively disperse from one habitat to another. Because the presence of humans adversely affects many species, habitat areas that lack roads or are inaccessible to humans are safer than human-accessible areas.

According to conservation biologists, it is more effective and, ultimately, more economical to employ landscape scale conservation strategies to preserve intact ecosystems in which

many species live than to try to preserve individual species. Conservation biologists generally consider it a higher priority to preserve areas with greater biological diversity.

Conservation biology includes two problem-solving approaches that save organisms from extinction: *in situ* and *ex situ* conservation. **In situ conservation**, which includes the establishment of parks and reserves, concentrates on preserving biological diversity in nature. A high priority of *in situ* conservation is identifying and protecting sites that harbor a great deal of diversity.

With increasing demands on land, *in situ* conservation cannot preserve all types of biological diversity. Sometimes only *ex situ* conservation can save a species. **Ex situ conservation** conserves individual species in human-controlled settings. Breeding captive species in zoos and storing seeds of genetically diverse plant crops are examples of *ex situ* conservation.

In situ conservation is the best way to preserve biological diversity

Protecting animal and plant habitats—that is, conserving and managing ecosystems as a whole—is the single best way to protect biological diversity. Most nations have set aside areas for wildlife habitats. Such natural ecosystems offer the best strategy for the long-term protection and preservation of biological diversity. Currently, more than 160,000 national parks, marine sanctuaries, wildlife refuges, forests, and other areas are protected throughout the world. Nearly 15% of the world's land area is protected, but only about 3% of ocean area is set aside.

Unfortunately, many protected areas have multiple uses that sometimes conflict with the goal of preserving species. National parks provide for recreational needs, for example, whereas national forests are used for logging, grazing, and mineral extraction. The mineral rights to many wildlife refuges are privately owned, and oil, gas, and other mineral development has occurred on some wildlife refuges.

Protected areas are not always an effective strategy to preserve biological diversity, particularly in developing countries where biological diversity is greatest, because there is little money or expertise to manage them. Another shortcoming of the world's protected areas is that many are in lightly populated mountain areas, tundra, and the driest deserts—places that often have spectacular scenery, but relatively few kinds of species. In reality, such remote areas are often designated reserves because they are unsuitable for commercial development.

In contrast, ecosystems in which biological diversity is greatest often receive little attention. More protected areas are urgently needed in tropical rain forests, the tropical grasslands and savannas of Brazil and Australia, and dry forests that are widely scattered around the world. Desert organisms are underprotected in northern Africa and Argentina, and the species of many islands and temperate river basins also need protection.

Many of these unprotected areas are part of what biologists have identified as the world's 36 **biodiversity hotspots** (FIG. 57-9). The hotspots collectively make up 2.3% of Earth's land but contain more than half of all vascular plant species and nearly 43% of the world's endemic mammal, bird, reptile, and amphibian species. More than 25% of the world's human population lives

in the hotspots. To be classified as a biodiversity hotspot, an area must have at least 1500 species of endemic vascular plants and must have lost at least 70% of its original and natural vegetation. Several international conservation organizations have partnered with many countries containing hotspots to support research and protect the areas from further degradation. At the same time, they address the needs of the indigenous people. Improving the conditions of hotspots helps to maintain important services for humans such as clean water and air, soil regeneration, flood control, food, medicines, and other natural resources. Not all conservation biologists support focusing limited conservation resources on protecting biodiversity hotspots because doing so ignores the many **ecosystem services** provided by entire ecosystems that are rapidly vanishing due to habitat destruction. For example, the vast boreal forests in Canada and Russia are critically important to the proper functioning of the global carbon and nitrogen cycles. Conservation organizations do not recognize them as hotspots, however, and these forests are being logged and replaced with monoculture plantings at unprecedented rates. Landscape ecology takes a larger view of ecosystem conservation.

Landscape ecology considers ecosystem types on a regional scale The subdiscipline of ecology that studies the connections in a heterogeneous **landscape** consisting of multiple interacting ecosystems is known as **landscape ecology**. Increasingly, biologists are focusing efforts on preserving biodiversity in landscapes. What, though, is the minimum ecosystem/landscape size needed to preserve species numbers and distributions?

One long-term study addressing this question in tropical rain forests is the Biological Dynamics of Forest Fragment Project (formerly the Minimum Critical Size of Ecosystems Project), which is studying a series of Amazonian rainforest fragments varying in size from 1 to 100 hectares (One hectare is equal to 2.471 acres.) (FIG. 57-10). Preliminary data from this study, which began in 1979, indicate that smaller forest fragments do not maintain their ecological integrity. For example, large trees near forest edges often die or are damaged from exposure to wind, desiccation (from lateral exposure of the forest fragment to sunlight), and invasion by parasitic woody vines. Biologists have documented that various species adapted to forest interiors do not prosper in the smaller fragments and eventually die out, whereas species adapted to forest edges invade the smaller fragments and thrive. The continuation of this research over 40 years allows scientists to study natural events, such as El Niño droughts, that add to natural disturbance and can affect fragmentation.

Unfortunately, human colonization, hunting, and other activities are threatening the Biological Dynamics of Forest Fragment Project itself. Recently, a 1100-km (683.1 mi) road was paved nearby, expanding agriculture, logging, and hunting opportunities. Should human expansion spread into the research site, the potential benefits that might be derived from understanding the effects of forest fragmentation will be lost.

To remedy widespread habitat fragmentation and its associated loss of biodiversity, conservation biologists have proposed linking isolated fragments with **habitat corridors**, strips of habitat connecting isolated habitat patches. Habitat corridors

Key Point

Biodiversity hotspots are areas of the world that are critically important because they contain a disproportionate number of the world's endemic species.

Figure 57-9 Biodiversity hotspots

Rich in endemic species, these hotspots are under pressure from the number of humans living in them.

Adapted from Miller, G.T., and S.E. Spoolman, *Living in the Environment*, 17th ed. (Brooks Cole/Cengage Learning, 2012): 243, Figure 10-27.

Data from Center for Applied Biodiversity Science at Conservation International.

PREDICT How could a large human population in a hotspot area be turned into an advantage?

allow wildlife to move about so they can feed, mate, and recolonize habitats after local extinctions take place. Research has also shown that habitat fragments linked by habitat corridors retain more native plant species than do isolated fragments.

Habitat corridors range from a local scale (such as an overpass that allows wildlife to cross a road safely) to a landscape scale that connects separate reserves. The minimum corridor width for landscape-scale corridors varies depending on the size of home ranges for various species. For example, to link two reserves and protect wolves in Minnesota, the corridor must have a minimum width of 12 km (7.2 mi), whereas the minimum corridor width for bobcats in South Carolina must be 2.5 km (1.5 mi).

The United Nations Educational, Scientific, and Cultural Organization (UNESCO) Program on Man and the Biosphere (MAB) has established **biosphere reserves** to protect biodiversity. Each reserve consists of three zones: core, buffer, and transition. The core zone contains a protected ecosystem and allows for nondestructive research and education. The surrounding buffer zone is used for environmental education, ecotourism, recreation, and research. The transition zone consists of local farms, fisheries, and towns where stakeholders

collaborate to oversee and sustainably develop the biosphere's resources. Maintaining biodiversity is a major principle of environmental sustainability.

Restoring damaged or destroyed habitats is the goal of restoration ecology Increasingly, countries are reclaiming disturbed lands and converting them into areas with high biological diversity. **Restoration ecology**, in which the principles of ecology are used to return a degraded environment to one that is more functional and sustainable, is an important part of in situ conservation. Costa Rica is an important success story. By the 1980s, ranchers had cleared so much forest to provide land for grazing and farmers had cleared so much land for growing coffee trees that only about 20% of Costa Rica's tropical forests remained. Then, this small, but ecologically important, country made a commitment to restore and protect its rich biodiversity. Economic and other incentives were offered for restoring and protecting its lands. Once again, forests cover more than 50% of its land area and Costa Rica has become a global leader in environmental sustainability and ecotourism (FIG. 57-11).

Figure 57-10 Biological Dynamics of Forest Fragment Project

Shown are 1-hectare and 10-hectare plots of a long-term (about three decades) study under way in Brazil on the effects of fragmentation on Amazonian rain forest. Plots with an area of 100 hectares are also under study, along with identically sized sections of intact forest, which are controls.

Figure 57-11 Restoration ecology and biodiversity conservation in Costa Rica

Costa Rica has won international awards for restoring its tropical forests and protecting its rich biodiversity. Its protected natural parklands (green) are surrounded by buffer zones (yellow), which are used for sustainable agriculture, cattle grazing, forestry, logging, fishing, and ecotourism. Adapted from Miller, G.T., and S.E. Spoolman, *Living in the Environment*, 17th ed. (Brooks Cole/Cengage Learning, 2012): 241, Figure 10-26.

One of the oldest and most extensive ecological restoration projects in the United States was undertaken in the early 1930s by the University of Wisconsin–Madison Arboretum. The university ecologists have developed several distinct natural communities on damaged agricultural land (FIG. 57-12). These communities include a tallgrass prairie, a xeric (dry) prairie, savannas, and several types of pine and maple forests native to Wisconsin. More than 300 species have been restored.

The government of New Zealand has partnered with the public and indigenous peoples, beginning in 1995, to restore the island Motuora to its native ecosystem. It had become a grassy, weedy grazing area. A model ecosystem plan combined with bottom-up approach implementation (plants, invertebrates, reptiles/birds) is in effect. Areas of the island were sprayed to remove non-native plants and many invasive animal species were relocated. Following a logical sequence, based on studies of less modified nearby islands and other information, more than 300,000 native trees were planted followed by less hardy

(a) The restoration of the prairie by the University of Wisconsin–Madison Arboretum was at an early stage in 1935. The men are digging holes to plant prairie grass sod.

(b) The prairie as it looks today. This picture was taken at about the same location as the 1935 photograph.

Figure 57-12 Restoring damaged lands

species under the growing tree canopies. Researchers report that the range and population size of tree-dwelling animals has improved, allowing them to gradually introduce rarer and endangered species. Restoration of disturbed lands not only creates biological habitats but also has additional benefits, such as the regeneration of soil damaged by agriculture or mining. Restoration ecology continues to be an important and expanding aspect of conservation biology.

Ex situ conservation attempts to save species on the brink of extinction

Zoos, aquaria, and botanical gardens are valuable because they provide the public with informal learning and education opportunities to understand the importance of biodiversity and conservation. These facilities work to save certain endangered species from extinction. Eggs are collected from nature, or the remaining few animals are captured and bred in zoos and other research facilities.

Artificial insemination and host mothering can be used to increase the number of offspring. In **artificial insemination** sperm can be collected from a suitable male of a rare species and used to impregnate a selected female, which may be located in another zoo, or even another country. In **host mothering** a female of a rare species is treated with fertility drugs, which cause her to produce multiple eggs. These eggs are collected, fertilized, and surgically implanted into females of a related but less rare species. These females later give birth to offspring of the rare species (see *Inquiring About: Novel Origins* in Chapter 50). Hormone patches are being developed to stimulate reproduction in endangered birds; the patch is attached under the female bird’s wing.

A few spectacular successes have occurred in captive-breeding programs, in which large enough numbers of a species have been produced to re-establish small populations in the wild. Conservation efforts, for example, let the bald eagle make a remarkable comeback in the contiguous states, and in 2007, the U.S. Fish and Wildlife Service (FWS) removed the bald eagle from the endangered list.

Attempting to save a species on the brink of extinction is usually expensive, and only a small proportion of endangered species can be saved. Moreover, zoos, aquaria, and botanical gardens do not have the space to try to save all endangered species. Conservation biologists must therefore set priorities on which species to attempt to save. Zoos have traditionally focused on large, charismatic animals, such as pandas, bald eagles, and whooping cranes, because the public is interested in them. However, such conservation efforts ignore millions of ecologically important species. Clearly, controlling unchecked human development so that species do not become endangered in the first place is a more effective way to protect and maintain natural habitat.

The Endangered Species Act provides some legal protection for species and habitats

In 1973, the *Endangered Species Act (ESA)* was passed in the United States, authorizing the FWS to protect endangered and threatened species in the United States and abroad. Most other

countries now have similar legislation. The FWS conducts a detailed study of a species to determine if it should be listed as endangered or threatened (TABLE 57-1). The ESA provides legal protection to listed species, reducing their danger of extinction. For example, the act makes it illegal to sell or buy any product made from an endangered or threatened species.

The ESA requires officials of the FWS to select critical habitats and design a recovery plan for each species listed. The recovery plan includes an estimate of the current population size, an analysis of what factors contributed to its endangerment, and a list of activities that may help the species recover.

The ESA is considered one of the strongest pieces of environmental legislation in the United States, in part because species are designated as endangered or threatened entirely on biological grounds. Economic considerations cannot influence the designation of endangered or threatened species. Biologists generally agree that as a result of passage of the ESA in 1973, fewer species became extinct than would have had the law not been passed.

The ESA is also a controversial piece of environmental legislation. For example, the ESA does not provide compensation for private property owners who suffer financial losses because they cannot develop their land if a threatened or endangered species lives there.

It currently takes several years for a candidate species with declining numbers to be listed as threatened or endangered. This backlog is due to both the high cost of evaluating each species and the limited funds allocated to the FWS for these studies. Meanwhile, dozens of species on the ESA’s “candidate list” have become extinct since 1973, without ever being classified as

Table 57-1 Organisms Listed as Endangered or Threatened in the United States, as of May 2017		
Type of Organism	Number of Endangered Species	Number of Threatened Species
Mammals	69	27
Birds	81	20
Reptiles	16	28
Amphibians	20	15
Fishes	92	72
Snails	40	12
Clams	75	14
Crustaceans	24	4
Insects	73	11
Spiders	12	0
Flowering plants	735	163
Conifers and cycads	1	3
Ferns, other plants	36	2
Corals	0	6
Lichens	2	0

Data from U.S. Fish and Wildlife Service.

threatened or endangered. Once an organism is listed as endangered, however, it has an excellent chance for survival. Over 99% of species protected by the ESA currently survive.

The ESA appears to be geared more to funding popular or unique endangered species than to saving the much larger number of less popular species that perform valuable ecosystem services. Less glamorous plants, fungi, bacteria and archaea, and insects, however, play central roles in ecosystems. Prokaryotes and fungi, for example, provide the critically important ecosystem service of breaking down dead organic materials into simple substances (CO₂, water, and minerals) that are subsequently recycled to plants and other autotrophs.

Conservation biologists and numerous conservation organizations support a stronger ESA to manage whole ecosystems and maintain complete biological diversity rather than attempt to save endangered species as isolated entities. This approach offers collective protection to many more declining species.

International agreements provide some protection for species and habitats

The *Convention on International Trade in Endangered Species of Wild Flora and Fauna* (CITES) is an international agreement that went into effect in 1975. Originally drawn up to protect endangered animals and plants considered valuable in the highly lucrative international wildlife trade, CITES bans hunting, capturing, and selling of endangered or threatened species and regulates trade of organisms listed as potentially threatened. Unfortunately, enforcement of this treaty varies from country to country, and even where enforcement exists, the penalties are often minimal. Public concern and negative media publicity, however, have had increasing impact on illegal trade in recent years.

The goals of CITES often stir up controversy over such issues as who actually owns the world's wildlife and whether global conservation concerns take precedence over competing local interests. These conflicts often highlight socioeconomic differences between wealthy consumers of products protected by CITES and poor people who trade the endangered organisms.

Another international treaty, the *Convention on Biological Diversity*, requires that each signatory nation inventory its own biodiversity and develop a **national conservation strategy**, a detailed plan for managing and preserving the biological diversity of that specific country.

- Which type of conservation measure, in situ or ex situ, helps the greatest number of species? Why?
- **CONNECT** Why is the U.S. Endangered Species Act controversial?

57.3 Deforestation

LEARNING OBJECTIVES

- 6 Discuss the ecosystem services of forests and describe the consequences of deforestation.
- 7 State at least three reasons why forests (particularly tropical rain forests) are disappearing today.

The most serious problem facing the world's forests and their biological diversity is **deforestation**, the permanent clearance of large expanses of forest for agriculture or other uses (**FIG. 57-13**). According to the UN Food and Agriculture Organization, between 2000 and 2010, forests declined by about 5.2 million hectares each year (an area equal to the size of Costa Rica).

The majority of the world's remaining forest landscapes are tropical rain forests and boreal forests. When these forests are destroyed, their valuable ecosystem services are no longer available to the environment or to people who depend on them. Deforestation increases soil erosion and thus decreases soil fertility. Soil erosion causes increased sedimentation of waterways, which harms downstream aquatic ecosystems by reducing light penetration, covering aquatic organisms, and filling in waterways. Uncontrolled soil erosion, particularly on steep deforested slopes, causes mudflows that endanger human lives and property and reduces production of hydroelectric power as silt builds up behind dams. In drier areas, deforestation can lead to the formation of deserts.

Deforestation contributes to the loss of biological diversity. Many species have limited ranges within a forest, particularly in the tropics, making these species especially vulnerable to habitat destruction or modification. Migratory species, such as birds and butterflies, also suffer from tropical deforestation. When original forests are destroyed, biodiversity is greatly diminished. If trees are subsequently replanted, the

Gary Braasch/Getty Images

Figure 57-13 Deforestation

level of biodiversity increases very slowly and is unlikely to approach previous levels of biodiversity.

By trapping and absorbing precipitation, forests on hill-sides and mountains help protect nearby lowlands from floods. When a forest is cut down, the watershed cannot absorb and hold water as well, and the total amount of surface runoff flowing into rivers and streams increases. This increased runoff not only causes soil erosion, but also puts lowland areas at extreme risk of flooding.

Deforestation may affect regional and global climate changes. Transpiring trees release substantial amounts of moisture into the air. This moisture falls back to the surface in the hydrologic cycle. When a large forest is removed, rainfall may decline, and droughts may become common in that region. Studies suggest that the local climate has become drier in parts of Brazil where tracts of the rain forest have been burned. Temperatures rise slightly in a deforested area because there is less evaporative cooling from the trees.

Deforestation increases global temperature by releasing carbon stored in the trees into the atmosphere as carbon dioxide, which enables the air to retain heat. The carbon in forests is released immediately if the trees are burned or more slowly when unburned parts decay. Deforestation is responsible for approximately 15% of all greenhouse gas emissions. If trees are harvested and logs are removed, roughly one-half of the forest carbon remains as dead materials (branches, twigs, roots, and leaves) that decompose, releasing carbon dioxide. When an old-growth forest is harvested, it may take 200 years for the replacement forest to accumulate the amount of carbon that was stored in the original forest.

Why are tropical rain forests continuing to disappear?

Most of the remaining undisturbed tropical rain forests, in the Amazon and Congo River basins of South America and Africa and in Indonesia, continue to be cleared and burned at a rate unprecedented in human history. Tropical rain forests are also being rapidly destroyed in southern Asia, Central America, and the Philippines.

Several studies show a strong statistical correlation between population growth and deforestation. More people need more food and fuel, so they clear forests for agricultural expansion and burn wood for personal use. However, tropical deforestation cannot be attributed simply to population pressures. The main causes of deforestation vary from place to place, and a variety of economic, social, and governmental factors interact to cause deforestation. Government policies sometimes provide incentives that favor the removal of forests. For example, in the late 1950s, the Brazilian government constructed the Belem–Brasilia Highway, which cut through the Amazon Basin and opened the Amazonian frontier for settlement (FIG. 57-14). Sometimes economic conditions encourage deforestation. The farmer who converts more forest to pasture can maintain a larger herd of cattle, which is a good hedge against inflation.

Although tropical deforestation is a complex problem, the immediate causes of deforestation in tropical rain forests

National Remote Sensing Centre Ltd/Science Source

Figure 57-14 Human settlements in Brazil's tropical rain forest

This satellite photograph shows numerous smaller roads extending perpendicularly from the main roads. As people settle along the roads, they clear out more and more forest (dark green) for their croplands and pastures (tans and pinks).

are subsistence agriculture, commercial logging, commercial plantations (palm oil, sugarcane, and bananas), and cattle ranching. Other reasons for the destruction of tropical forests include the development of hydroelectric power, which inundates large areas of forest and mining, particularly when ore smelters burn charcoal produced from rainforest trees.

Subsistence agriculture, in which a family produces enough food to feed itself, accounts for nearly 50% of tropical deforestation. In many developing countries where tropical rain forests are located, many people do not own the land on which they live and work and must clear the forest to grow food. Land reform in Brazil, Madagascar, Mexico, the Philippines, Thailand, and many other countries is slowly easing some of the pressure of subsistence farmers on tropical forests as deforestation is decoupled from economic growth.

Subsistence farmers often follow loggers' access roads, cut down the trees, burn the area, and plant crops immediately. This method is known as **slash-and-burn agriculture**. Yields from the first crop are often quite high because the nutrients that were in the trees are now available in the soil. In a few years, however, soil productivity declines, and the farmer must move to a new part of the forest and repeat the process. Cattle ranchers often claim the abandoned land because it can still support livestock.

Slash-and-burn agriculture carried out on a small scale, with periods of 20 to 100 years between cycles, is sustainable. The forest regrows rapidly after a few years of farming. However, when millions of people try to obtain a living in this way, the land is not allowed to lie uncultivated long enough to recover. Globally, at least 180 million subsistence farmers obtain a living from slash-and-burn agriculture.

About 14% of tropical deforestation is the result of commercial logging, and vast tracts of tropical rain forests, particularly in Southeast Asia, are harvested for export abroad. Some tropical countries still allow commercial logging to proceed much faster than is sustainable because it supplies them with much-needed revenues. In the final analysis, uncontrolled tropical deforestation does not contribute to economic development; rather, it reduces or destroys the value of an important natural resource.

Approximately 10% of tropical rainforest destruction is carried out to provide open range-land for cattle. Cattle ranching is particularly important in Central America. Much of the beef raised on these ranches, which foreign companies often own, is exported to restaurant chains in North America and Europe. After the forests are cleared, cattle graze on the land for as long as 20 years, after which time the soil fertility is depleted. When that occurs, shrubby plants, or *scrub savanna*, take over the range.

Why are boreal forests disappearing?

Tropical rain forests are not the only forests at risk from deforestation. Extensive logging of undisturbed boreal forests began in the late 1980s and continues today. Coniferous evergreen trees such as spruce, fir, cedar, and hemlock dominate these northern forests of Alaska, Canada, Scandinavia, and northern Russia.

Boreal forests, harvested primarily by clear-cut logging, are currently the primary source of the world's industrial wood and wood fiber. More than 1 million hectares (2.5 million acres)

of Canadian forests are logged annually, and most of Canada's forests are under logging tenures. (*Tenures* are agreements between provinces and companies that give companies the right to cut timber.) Many of the logged forests are replanted, to grow and be harvested in the future, but biodiversity is significantly reduced. Canada is the world's biggest timber exporter, and most of its forest products are exported to China and the United States. In 2010, Canada reached an agreement between loggers and environmentalists to protect a huge part of the Canadian boreal forest, 1.4 billion acres of wilderness containing mostly never-harvested woodland. Extensive tracts of boreal forests in Russia are also harvested as evidenced by satellite imagery, although exact estimates are unavailable. Alaska's boreal forests may also be at risk if the U.S. government increases logging on public lands there in the near future.

CHECKPOINT 57.3

- What are three ecosystem services that forests provide?
- What are two reasons for deforestation in tropical rain forests? What is the main reason for deforestation of boreal forests?

57.4 Climate Change

LEARNING OBJECTIVES

- 8 Name at least three greenhouse gases and explain how greenhouse gases contribute to climate change.
- 9 Describe how climate change may affect sea level, precipitation patterns, organisms (including humans), and food production.

Earth's average temperature is based on daily measurements from several thousand land-based meteorological stations around the world as well as data from weather balloons, orbiting satellites, transoceanic ships, and hundreds of sea-surface buoys with temperature sensors. The 1990s was the warmest decade of the 20th century, and the early 2000s continued the warming trend. Sixteen of the 17 warmest years have been recorded since 2000 (**FIG. 57-15**). Earth's rapidly changing climate imposes stress on many living organisms and is already having a negative effect on biological diversity.

Scientists worldwide have studied **climate change** for several decades. As the evidence has accumulated, a strong consensus was reached that the 21st century will experience significant rapid climate change and that this change has been caused mainly by human activities. Governments around the world organized the United Nations' Intergovernmental Panel on Climate Change (IPCC) in 1988 to review all published literature about global climate change, especially recent research, and provide an update of knowledge on the scientific, technical, and socioeconomic aspects of climate change. Observed and projected effects of climate change in each IPCC report have been progressively worse.

The 2013 IPCC Fifth Assessment Report concluded that human-produced air pollutants caused most of the climate change

Figure 57-15 Mean annual global temperature, 1960 to 2017
Data are presented as surface temperatures (°C) for 1960, 1965, and every year thereafter. The measurements, which naturally fluctuate, clearly show the warming trend of the last several decades. Data from Surface Air Temperature Analysis, Goddard Institute for Space Studies, NASA.

and increased ocean water temperatures observed during the prior 55 years. The IPCC report projects global surface temperature increase is likely to exceed 1.5 to 2.0°C (2.7 to 3.6°F) by the year 2100. In addition, the global ocean will continue to warm, which will affect ocean circulation, and will also undergo further acidification.

The sixth IPCC Assessment Report is currently being drafted. Two special reports are also being prepared for release in 2019: *Special Report on Oceans and Cryosphere in a Changing Climate* and *Climate Change and Land: An IPCC Special Report on Climate Change, Desertification, Land Degradation, Sustainable Land Management, Food Security, and Greenhouse Gas Fluxes in Terrestrial Ecosystems*.

Global warming is melting land ice and expanding sea water. Satellite sea level observations from NASA have recorded an increase of 85.5 mm (3.4 in.) from 1993 to the beginning of 2017. Sea levels will rise more rapidly during the 21st century (compared with observations from 1970 to 2016) as shrinking of glaciers and ice sheets continues to increase rapidly. As a result, Earth will likely become warmer during the 21st century than it has been for several million years.

Greenhouse gases cause climate change

The World Meteorological Organization recently reported a 29% increase in the warming effect of greenhouse gases between 1990 and 2010; carbon dioxide accounted for 80% of this increase. Carbon dioxide (CO₂), methane (CH₄), and nitrous oxide (N₂O) are the three most prevalent and long-lived greenhouse gases, excluding water vapor. Surface ozone (O₃) and hydrochlorofluorocarbons (HCFCs) also continue to

accumulate in the atmosphere as a result of human activities (TABLE 57-2). The concentration of atmospheric CO₂ has increased by nearly 40% since the start of the industrial era in 1750. In early 1917, it was recorded at 405 parts per million (FIG. 57-16). Burning carbon-containing fossil fuels—coal, oil, and natural gas—accounts for about three-fourths of human-made carbon dioxide emissions to the atmosphere. Land conversion, such as when forests are logged or burned, also releases carbon dioxide. Trees normally remove carbon dioxide from the atmosphere during photosynthesis, but tree removal prevents this process.

Climate change occurs because greenhouse gases absorb infrared radiation (heat) in the atmosphere. This absorption slows the natural heat flow into space, warming the lower atmosphere. Some of the heat from the lower atmosphere is transferred to the ocean and raises its temperature as well. This atmospheric retention of heat is a natural phenomenon that has made Earth habitable for its millions of species.

Because carbon dioxide and other gases trap the sun's radiation somewhat like glass does in a greenhouse, the natural trapping of heat in the atmosphere is called the **greenhouse effect**, and the gases that absorb infrared radiation are known as **greenhouse gases**. This natural heating of the atmosphere prevents Earth from becoming a frozen planet. However, the additional warming produced when increased levels of gases produced by human activities absorb additional infrared radiation, called the **enhanced greenhouse effect**, has potentially catastrophic implications as atmospheric and ocean temperatures continue to rise (FIG. 57-17).

Although current rates of fossil fuel combustion and deforestation are high, causing the carbon dioxide level in the atmosphere to increase markedly, scientists think that the

Table 57-2 Changes in Selected Atmospheric Greenhouse Gases, Preindustrial Times to Present

Gas	Estimated Preindustrial Concentration	Present Concentration
Carbon dioxide	288 ppm*	400 ppm
Methane	848 ppb†	1866 ppb
Nitrous oxide	285 ppb	324 ppb
Tropospheric ozone	25 ppb	34 ppb
CFC-12	0 ppt‡	530 ppt
CFC-11	0 ppt	237 ppt

Note: The preindustrial value is for the 17th and 18th centuries.

Data from Carbon Dioxide Information Analysis Center, Environmental Sciences Division, Oak Ridge National Laboratory.

* ppm = parts per million

† ppb = parts per billion

‡ ppt = parts per trillion

Figure 57-16 Carbon dioxide in the atmosphere, 1960 to 2017

Note the steady increase in the concentration of atmospheric carbon dioxide. Measurements are taken at the Mauna Loa Observatory, Hawaii, far from urban areas where factories, power plants, and motor vehicles emit carbon dioxide. Data from Scripps Institution of Oceanography, University of California, La Jolla, California.

warming trend is slower than the increasing level of carbon dioxide might indicate. The reason is that water requires more heat to raise its temperature than gases in the atmosphere do. (Recall the high specific heat of water discussed in Chapter 2.) As a result, the ocean takes longer to warm than the atmosphere. Most climate scientists think that warming will be more pronounced in the second half of the 21st century than in the first half.

Methane gas, the second most prevalent greenhouse gas, has increased nearly 160% since 1750, mostly due to cattle grazing, rice planting, fossil fuel exploitation, and landfills. Human activities currently account for 60% of methane emissions, whereas nearly 40% of emissions are naturally occurring. The natural methane emissions are also growing and are expected to increase still more as northern permafrost thaws and tropical wetland emissions increase.

Nitrous oxide (N_2O) is now the third most important greenhouse gas and is found at levels 20% higher than in 1750. Its concentration is increasing rapidly due to use of nitrogen-containing fertilizers and manure. The effect of nitrous oxide over the past century is nearly 300 times greater than the effect of equal emissions of carbon dioxide and is contributing to the destruction of the stratospheric ozone layer. This layer protects us from harmful solar ultraviolet rays. (See *Inquiring About: Stratospheric Ozone Depletion from Industrial Chemicals*.)

What are the probable effects of climate change?

We now consider some of the probable effects of climate change, including changes in sea level; changes in precipitation patterns; effects on organisms, including humans; and

effects on agriculture. These changes will persist for centuries because many greenhouse gases remain in the atmosphere for hundreds of years. Furthermore, even after greenhouse gas concentrations have stabilized, scientists think that Earth's mean surface temperature will continue to rise because the ocean adjusts to climate change on a delayed time scale.

With climate change, the global average sea level is rising

As Earth's overall temperature increases, major thawing of glaciers and the polar ice caps is taking place. In addition to sea-level rise caused by the retreat of glaciers and thawing of polar ice, the sea level will rise due to thermal expansion of the warming ocean. Water, like other substances, expands as it warms.

The IPCC estimates that sea level will rise 18 to 59 cm (0.6 to 1.9 ft) by 2100 and notes that it could be even higher. Such an increase will flood low-lying coastal areas, such as parts of southern Louisiana and south Florida. Coastal areas that are not inundated will likely suffer erosion and other damage from more frequent and more intense weather events such as hurricanes. Countries particularly at risk include

Bangladesh, Egypt, Vietnam, Mozambique, and many island nations such as the Maldives.

With climate change, precipitation patterns will change

Computer simulations of weather changes from climate warming indicate that precipitation patterns will be altered, causing some areas such as midlatitude continental interiors to have more frequent droughts. At the same time, heavier snowstorms and rainstorms may cause more frequent flooding in other areas. Changes in precipitation patterns could impact the availability and quality of fresh water in many places. Arid or semiarid areas, such as the Sahel region just south of the Sahara Desert, may have the most serious water shortages as the climate warms. Closer to home, water experts predict more water shortages in the western United States because warmer winter temperatures will cause more precipitation to fall as rain rather than snow; melting snow currently provides 70% of stream flows in that region during summer months.

The frequency and intensity of storms over warm surface waters may also increase. A computer model developed by the National Oceanic and Atmospheric Administration (NOAA) scientists predicts how climate change may affect hurricanes. When the model was run with a sea-surface temperature 2.2°C warmer than today, more intense hurricanes resulted. (The question of whether hurricanes will occur *more frequently* in a warmer climate continues to be studied.) Increases in storm frequency and intensity are expected because as the atmosphere warms, more water evaporates, which in turn releases more energy into the atmosphere. (Recall the discussion of water's heat of vaporization in Chapter 2.) This energy generates unusually powerful storms.

Key Point

Greenhouse gases accumulating in the atmosphere are causing an enhanced greenhouse effect, resulting in climate change. Human activity is largely responsible for these changes.

Figure 57-17 Enhanced greenhouse effect

The buildup of carbon dioxide and other greenhouse gases in the atmosphere absorbs some of the outgoing infrared (heat) radiation and redirects it back to Earth's surface. As a result, the atmosphere, land, and ocean are warming.

CONNECT How can we slow the accumulation of greenhouse gases in the atmosphere?

With climate change, the ranges of organisms are changing Dozens of studies report on the effects of climate change on organisms, from flowering times in plants to breeding times in birds. For example, researchers determined that populations of zooplankton in the California Current have declined 80% since 1951, apparently because the current has warmed slightly. (The California Current flows from Oregon southward along the California coast.) The decline in zooplankton has affected the entire ecosystem's food web, and populations of seabirds and plankton-eating fishes have also declined.

Warmer temperatures in Antarctica—since 1960, the average annual temperature on the Antarctic Peninsula has increased 2.6°C (5°F)—have contributed to reproductive failure in Adélie penguins. The birds normally lay their eggs in snow-free rocky outcrops, but the warmer temperatures have caused increased snowfall (recall that warmer air holds more moisture), which melts when the birds incubate the eggs. The melted snow forms cold pools of slush that kill the developing chick embryos.

Biologists generally agree that climate change will have an especially severe effect on plants, which cannot migrate as quickly as animals when environmental conditions change. (The speed of seed dispersal has definite limitations.) During past climate changes, such as during the glacial retreat that took place some 12,000 years ago, the upper limit of dispersal for tree species was probably 200 km (124 mi) per century. If Earth warms as much during the 21st century as projections indicate, the ranges for some temperate tree species may shift northward as much as 480 km (300 mi).

The U.S. Department of Agriculture reports hardiness zones, based on the average low temperature in an area. Hardiness zones, which indicate which plants will do well at different locations around the country, have already shifted considerably over the past 30 years.

Each species reacts to changes in temperature differently. In response to climate change, some species will probably become extinct, particularly those with narrow temperature requirements, those confined to small reserves or parks, and those living in fragile ecosystems. Other species may survive in greatly reduced numbers and ranges. Ecosystems considered most vulnerable to species loss in the short term are polar seas, coral reefs and atolls, prairie wetlands, coastal wetlands, tundra, boreal forests, tropical forests, and mountains, particularly alpine tundra.

In response to climate change, some species may disperse into new environments or adapt to the changing conditions in their present habitats. Climate change may not affect certain species, whereas other species may emerge as winners, with greatly expanded numbers and ranges. Those considered most likely to prosper include weeds, pests, and disease-carrying organisms, all of which are generalists that are already common in many different environments.

Climate change will have a more pronounced effect on human health in developing countries Data linking climate change and human health problems continue to accumulate. Since 1950, the United States has experienced an increased frequency of extreme heat-stress events, which are extremely hot, humid days during summer months. Heat-related deaths among elderly and other vulnerable people have been increasing now for many years worldwide.

Climate change has also affected human health indirectly. Mosquitoes and other disease carriers have expanded their range into the newly warm areas and are spreading malaria, Zika fever, dengue fever, yellow fever, chikungunya infection, Rift Valley fever, and viral encephalitis. As many as 50 million to 80 million additional cases of malaria are predicted to occur annually in tropical, subtropical, and temperate areas.

High-income countries are less vulnerable to such disease outbreaks because of better housing (which keeps mosquitoes outside), medical care, pest control, and public health measures such as water treatment plants. Dengue fever, however, has been increasing in Texas and the Florida Keys. The

Inquiring About

Stratospheric Ozone Depletion from Industrial Chemicals

The **stratosphere**, which encircles planet Earth some 10 to 45 km (6 to 28 mi) above the surface, contains a layer of **ozone (O₃)**. The ozone layer shields Earth's surface from about 95% of the harmful ultraviolet (UVA and UVB) radiation from the sun (see Figure 1). Ozone is a form of oxygen that is a human-made pollutant in the lower atmosphere, but is a naturally produced, essential part of the stratosphere. Ozone in the lower atmosphere is converted back to oxygen in a few days and so does not replenish the ozone depleted in the stratosphere.

A slight thinning in the ozone layer over Antarctica forms naturally for a few months each year. In 1985, however, scientists observed more thinning than usual. This increased ozone thinning, which begins each September, is commonly referred to as the "ozone hole" (see Figure 2). During the 1990s, the ozone-thinned area continued to grow, and by 2000 it had reached the record size of 28.3 million km² (11.3 million mi²), larger than the North American continent.

Certain chemicals, such as chlorine- and bromine-containing substances, catalyze ozone destruction, destroying stratospheric ozone. The primary chemicals responsible for ozone loss in the stratosphere are a group of chlorine compounds called *chlorofluorocarbons (CFCs)*, which were used as propellants in aerosol cans, coolants in air conditioners and refrigerators, and solvents and cleaners for the electronics industry. Additional compounds that also attack ozone include halocarbons (used in many fire extinguishers), methyl bromide (a pesticide), methyl chloroform (an industrial solvent), and carbon tetrachloride (used in many industrial processes, including the manufacture of pesticides and dyes).

After release into the troposphere (lowest part of Earth's atmosphere), CFCs and similar compounds slowly drift up to the stratosphere. There, ultraviolet radiation breaks them down, releasing chlorine. (Similarly, methyl bromide releases bromine.)

The thinning in the ozone layer over Antarctica occurs annually between September and November (spring in the Southern Hemisphere). At this time, two important conditions occur: sunlight returns to the polar region, and the *circumpolar vortex*, a mass of cold air that circulates around the southern polar region and isolates it from the warmer air in the rest of the planet, is well developed.

The cold air causes polar stratospheric clouds to form; these clouds contain ice crystals to which chlorine and bromine adhere, making them available to destroy ozone. The sunlight promotes the chemical reaction in which chlorine or bromine breaks ozone molecules apart, converting them into O₂ molecules. The chemical reaction in which ozone is destroyed does not alter the chlorine or bromine, and thus a single chlorine or bromine atom breaks down many thousands of ozone molecules. The chlorine and bromine remain in the stratosphere for many years. When the circumpolar vortex breaks up each year, the ozone-depleted air spreads northward, diluting ozone levels in the stratosphere over New Zealand, Australia, South America, and South Africa.

As the ozone layer is depleted, more ultraviolet radiation reaches Earth's surface. Increased levels of UV radiation disrupt ecosystems. For example, the productivity of Antarctic phytoplankton, the microscopic drifting algae that are the base of the Antarctic food web, has declined from increased

exposure to UVB. Biologists have also documented direct damage to natural populations of Antarctic fish. High levels of UV radiation may also damage crops and forests. Excessive exposure to UV radiation has been linked to human health problems, such as cataracts, severe sunburns, skin cancer, and a weakened immune system.

If ozone were to disappear from the stratosphere, Earth would become unlivable for most forms of life. The world's nations have addressed this serious environmental problem. In 1987, representatives from many countries signed the **Montreal Protocol**, an agreement that limited production of CFCs. Industrial companies that manufacture CFCs quickly developed substitutes.

International cooperation has continued to be a major force in repairing the ozone layer. Production of CFCs, carbon tetrachloride, and methyl chloroform has been completely phased out in the United States and other countries. Methyl bromide was phased out in 2015 in most countries. Hydrochlorofluorocarbons will be phased out in 2020 in high-income countries and in 2030 in lower-income countries. Satellite measurements taken in 1997 provided the first evidence that the levels of ozone-depleting chemicals were starting to decline in the stratosphere. International agreements regarding ozone have now been signed by all independent countries in the world (about 196). According to recent research, the ozone hole over Antarctica shrank more than 4 million square km between 2000 and 2015. The researchers reported that more than 50% of the shrinkage was due to a decrease in atmospheric chlorine. As atmospheric chlorine levels decrease, stratospheric ozone levels may return to 1980 levels by midcentury and 1950 levels may be reached by the end of this century.

Figure 1 Ultraviolet radiation and the ozone layer. Stratospheric ozone absorbs 99% of incoming UV radiation, effectively shielding Earth's surface (*left*). When stratospheric ozone is reduced (*right*), more high-energy UV radiation penetrates the atmosphere and reaches the surface, where it harms organisms. Stratospheric ozone thinning is accelerated by certain human-produced chemical compounds containing chlorine or bromine.

Figure 2 Ozone thinning. A computer-generated image of part of the Southern Hemisphere, taken in 2015, showing ozone thinning (*purple and blue areas*). The ozone-thinned area is moved about by air currents. (Dobson units measure stratospheric ozone. They are named after British scientist Gordon Dobson, who studied ozone levels over Antarctica during the late 1950s.)

Centers for Disease Control and Prevention recently reported a strain of dengue fever unique to the Florida Keys, indicating that the disease has been evolving in the region for many years. In 2012, the United States reported a 70% increase in cases of dengue fever. Mexico has recognized thousands of new cases of dengue fever, especially in the Yucatan and surrounding areas where tourism is prevalent.

Researchers report that the Zika virus epidemic of 2015–2016, which spread rapidly from South America to Mexico, Florida, and Puerto Rico, was aided by El Niño and by higher temperatures. As temperatures continue to increase, many areas of the United States will likely face more mosquito-active days, increasing the spread of Zika and other mosquito-borne diseases.

Climate change will increase problems for agriculture

Numerous studies show that the rising sea level will inundate river deltas, which are some of the world's best agricultural lands. The Nile River (Egypt), Mississippi River (United States), and Yangtze River (China) are examples of river deltas that have been studied. Certain agricultural pests and disease-causing organisms will probably proliferate. As mentioned earlier, climate change will likely increase the frequency and duration of droughts and, in some areas, crop-damaging floods.

On a regional scale, current climate-change models forecast that agricultural productivity will increase in some areas and decline in others. Models have suggested that Canada and Russia will increase their agricultural productivity in a warmer climate, whereas tropical and subtropical regions, where many of the world's poorest people live, will decline in agricultural productivity. Central America and Southeast Asia may experience some of the greatest declines in agricultural productivity.

We know how to prevent emission of greenhouse gases, for example, by reducing use of fossil fuels and replacing them with low-carbon renewable energy resources and solar energy (FIG. 57-18). We are also aware of strategies for removing excess carbon dioxide from the atmosphere, for example, by protecting wetlands and planting trees that store CO₂. The question is whether the global community of nations will work together to solve this very serious problem effectively, as they are doing for the problem of stratospheric ozone depletion.

The Future?

We hope that your study of biology has helped you understand that we humans are interdependent with millions of species of other organisms: our fellow companions on Planet Earth. We have impacted the biosphere more than any other species, and we have seriously disrupted its fragile web of interconnected ecosystems. We are not immune to the environmental damage that we have caused. In fact, we will share the fate of other species on the planet.

We humans differ from other organisms, however, in our capacity to comprehend and reflect on the consequences of

our actions and to alter our behavior accordingly. Humans, both individually and collectively, can bring about positive changes through integrating science and technology with the needs of society. Our commitment to sustainable living and increased awareness of developing issues, locally and globally, are essential to ensuring the biosphere's survival. The fate of future generations and of the biosphere depends on our willingness to learn, make informed decisions, and take action.

CHECKPOINT 57.4

- What is the enhanced greenhouse effect? What causes the enhanced greenhouse effect?
- **PREDICT** What are some of the significant problems that climate change may cause during the 21st century?

Prevention

Cut fossil fuel use (especially coal).

Shift from coal to natural gas.

Put a price on greenhouse gas emissions.

Improve energy efficiency.

Shift to renewable energy resources.

Transfer energy efficiency and renewable energy technologies to developing countries.

Reduce deforestation.

Use more sustainable agriculture and forestry.

Reduce poverty.

Slow population growth.

Cleanup

Remove CO₂ from smokestack and vehicle emissions.

Store (sequester) CO₂ by planting trees.

Sequester CO₂ in soil by using no-till cultivation and taking cropland out of production.

Sequester CO₂ deep underground (with no leaks allowed).

Sequester CO₂ in the deep ocean (with no leaks allowed).

Repair leaky natural gas pipelines and facilities.

Use animal feeds that reduce CH₄ emissions from cows (belching).

Figure 57-18 Slowing climate change: solutions

This figure shows some strategies we could use to slow atmospheric warming. Reducing the use of fossil fuel, especially coal, is a major prevention strategy. Shifting to renewable energy resources, including solar energy, is another critical action for decreasing greenhouse gas emissions. Because trees and wetlands remove carbon dioxide from the atmosphere, protecting forests and wetlands and planting trees will reduce carbon dioxide in the atmosphere. Adapted from Miller, G.T., and S.E. Spoolman, *Living in the Environment*, 17th ed. (Brooks Cole/Cengage Learning, 2012): 513, Figure 19-16.

Summary: Focus on Learning Objectives

57.1 The Biodiversity Crisis (page 1242)

1 Identify various levels of biodiversity: genetic diversity, species richness, and ecosystem diversity.

- **Genetic diversity** is the genetic variety within a species, both within a given population and among geographically separate populations. **Species richness** is the number of species of archaea, bacteria, protists, plants, fungi, and animals. **Ecosystem diversity** is the variety of Earth's ecosystems, such as forests, prairies, deserts, lakes, coastal estuaries, and coral reefs.

2 Distinguish among threatened species, endangered species, and extinct species.

- A species' **extinction** occurs when its last individual member dies. A species whose severely reduced numbers throughout all or a significant part of its **range** put it in imminent danger of extinction is classified as an **endangered species**. When extinction is less imminent but the population is quite small, a species is classified as a **threatened species**.

3 Discuss at least four causes of declining biological diversity and identify the most important causes.

- Human activities that reduce biological diversity include habitat loss and **habitat fragmentation**, pollution, introduction of **invasive species**, pest and predator control, illegal commercial hunting, and **commercial harvest**. Of these, habitat loss and fragmentation are the most significant.

57.2 Conservation Biology (page 1248)

4 Define conservation biology and compare in situ and ex situ conservation measures.

- **Conservation biology** is the study of how humans affect organisms and of the development of ways to protect biological diversity.
- Efforts to preserve biological diversity in the wild, known as **in situ conservation**, are urgently needed in the world's **biodiversity hotspots**. Increasingly, biologists are focusing efforts on preserving biodiversity in entire ecosystems and **landscapes**, which consist of multiple interacting ecosystems.
- **Ex situ conservation** involves conserving individual species in human-controlled settings. Breeding captive species in zoos and storing seeds of genetically diverse plant crops are examples.

5 Describe the benefits and shortcomings of the U.S. Endangered Species Act and the Convention on International Trade in Endangered Species of Wild Flora and Fauna.

- The *Endangered Species Act (ESA)* authorizes the U.S. Fish and Wildlife Service to protect endangered and threatened species, both in the United States and abroad. Conservationists would like to strengthen the ESA to manage whole ecosystems rather than endangered species and individual entities.
- At the international level, the *Convention on International Trade in Endangered Species of Wild Flora and Fauna (CITES)* protects endangered animals and plants considered valuable in the highly lucrative international wildlife trade. Enforcement varies from country to country; where

enforcement exists, penalties are not severe, so illegal trade in rare species continues.

57.3 Deforestation (page 1253)

6 Discuss the ecosystem services of forests and describe the consequences of deforestation.

- Forests provide many **ecosystem services**, including wildlife habitat, protection of watersheds, prevention of soil erosion, moderation of climate, and protection from flooding.
- **Deforestation** is the temporary or permanent clearance of forests for agriculture or other uses. Deforestation increases soil erosion and decreases soil fertility; contributes to loss of biological diversity; adversely affects watersheds; and may affect regional and global climate changes.

7 State at least three reasons why forests (particularly tropical rain forests) are disappearing today.

- Forests are destroyed to provide subsistence farmers with agricultural land, to produce timber, to provide open rangeland for cattle, and to supply fuel wood. **Subsistence agriculture**, in which a family produces enough food to feed itself, accounts for much of tropical rainforest deforestation. Extensive logging of boreal forests in Alaska, Canada, and Russia is the world's primary source of industrial wood and wood fiber.
- In **slash-and-burn agriculture**, trees are cut down and burned so that crops can be grown in the soil. Yields from the first crop are high because the nutrients that were in the trees are now available in the soil. When soil productivity declines, the farmer moves to a new part of the forest and repeats the process.

57.4 Climate Change (page 1255)

8 Name at least three greenhouse gases and explain how greenhouse gases contribute to climate change.

- **Greenhouse gases**—carbon dioxide, methane, nitrous oxide, surface ozone, and chlorofluorocarbons—cause the **greenhouse effect**, in which the atmosphere retains heat and warms Earth's surface. Increased levels of human-produced greenhouse gases in the atmosphere are causing concerns about an **enhanced greenhouse effect**, which is additional warming produced by increased levels of gases that absorb infrared radiation.

9 Describe how climate change may affect sea level, precipitation patterns, organisms (including humans), and food production.

- During the 21st century, **climate change** is causing a rise in sea level. Precipitation patterns are changing, resulting in more frequent droughts in some areas and more frequent flooding in other areas.
- Biologists think that climate change will cause some species to go extinct, some to be unaffected, and others to expand their numbers and ranges. Data linking climate change and human health problems (particularly in developing countries) are accumulating.
- Problems for agriculture include increased flooding, increased droughts, and declining agricultural productivity in tropical and subtropical areas.

Test Your Understanding

Know and Comprehend

- Which of the following statements about extinction is *not* correct? (a) extinction is the permanent loss of a species (b) extinction is a natural biological process (c) once a species is extinct, it never reappears (d) human activities have little impact on extinctions (e) thousands of plant and animal species are currently threatened with extinction
- An endangered species (a) is severely reduced in number (b) is in imminent danger of becoming extinct throughout all or a significant part of its range (c) usually does not have reduced genetic variability (d) is not in danger of extinction in the foreseeable future (e) a and b
- The most important reason for declining biological diversity is (a) air pollution (b) introduction of foreign (invasive) species (c) habitat destruction and fragmentation (d) illegal commercial hunting (e) commercial harvesting
- Habitat corridors (a) surround a given habitat (b) cut through a continuous habitat, producing an edge effect (c) vary in width depending on the species they are designed to protect (d) are an important strategy of ex situ conservation (e) have been widely adopted by restoration ecologists
- In situ conservation (a) includes breeding captive species in zoos (b) includes seed storage of genetically diverse crops (c) concentrates on preserving biological diversity in the wild (d) focuses exclusively on large, charismatic animals (e) a and b
- Restoration ecology (a) is the study of how humans impact organisms (b) returns a degraded environment as close as possible to its former state (c) is an example of ex situ conservation (d) has been used to successfully reverse the decline in amphibian populations (e) is an important provision of the Endangered Species Act
- About 60% of tropical rainforest deforestation is the result of (a) commercial logging (b) cattle ranching (c) hydroelectric dams (d) mining (e) subsistence agriculture
- Climate change occurs because (a) carbon dioxide and other greenhouse gases react chemically to produce excess heat (b) Earth has too many greenhouses and other glassed buildings (c) volcanic eruptions produce large quantities of sulfur and other greenhouse gases (d) carbon dioxide and other greenhouse gases trap infrared radiation in the atmosphere (e) carbon dioxide and other greenhouse gases allow excess heat to pass out of the atmosphere
- CONNECT** What gas is a human-made pollutant in the lower (surface) atmosphere but a natural and beneficial gas in the stratosphere? (a) CO₂ (b) CH₄ (c) O₃ (d) CFCs (e) N₂O
- Where is stratospheric ozone depletion most pronounced? (a) over Antarctica (b) over the equator (c) over South America (d) over North America and Europe (e) over Alaska and Siberia

Apply and Analyze

- Why might captive-breeding programs that reintroduce species into natural environments fail?
- CONNECT** Conservation biologists often say that their discipline is less about biology than it is about economics and human decision making. What do you think that they mean?
- A more descriptive name for *Homo sapiens* is *Homo dangerous*. Explain this specific epithet, given what you have learned in this chapter.

Evaluate and Synthesize

- EVOLUTION LINK** Because new species will eventually evolve to replace those that humans are driving to extinction, why is declining biological diversity such a threat?
- EVOLUTION LINK** Biologists have wondered how introduced species that would probably have limited genetic variation (due to the founder effect) survive and adapt so successfully that they become invasive. Part of the answer may be that invasive species are the result of multiple introductions instead of a single one. Explain how multiple introductions from a species' native area to an introduced area could increase that species' invasion success.
- EVOLUTION LINK** Conservation biologists have altered the evolution of salmon populations in captive-breeding programs. Wild female salmon tend to produce fewer but larger eggs because the large eggs contain more nutrients for the offspring than smaller eggs, giving each individual a greater chance to survive. After just a few generations, however, captive-bred females now lay greater numbers of small eggs. Suggest a possible adaptive advantage for many small eggs in the captive-bred environment. What would you predict regarding the reproductive success of captive-bred females released in the wild?
- INTERPRET DATA** Study the graph, which shows the combined effects of various factors on biological diversity in 12 different terrestrial and aquatic ecosystems. Which factor is most important overall? Why do you think that climate change and increasing atmospheric CO₂ are represented as separate factors? What is nitrogen pollution? Adapted from Sala, O.E., et al., *Science*, Vol. 287 (2000).

- SCIENCE, TECHNOLOGY, AND SOCIETY** If you were given the task of developing a policy for the United States to deal with global climate change during the next 50 years, what would you propose? Explain your answer by describing how science, technology, and society would play a role in your policy.

Classification of Organisms

The system of cataloging organisms used in this book is described in Chapter 1 and in Chapters 23 through 32. In this eleventh edition of *Biology*, we use the three-domain classification. The three domains are Bacteria, Archaea, and Eukarya (eukaryotes). We also discuss the five “supergroups” of eukaryotes based on molecular data. The kingdoms Plantae, Fungi, and Animalia are assigned to domain Eukarya. The protists are members of domain Eukarya, but are no longer considered a kingdom. We assign them to several supergroups.

In this classification overview, we have included select groups. (We have also omitted many groups, especially extinct ones.) We have omitted viruses from this survey because they are not considered living organisms and are not assigned to any of the three domains.

PROKARYOTES

Prokaryotes are distinguished from eukaryotes by their smaller ribosomes and absence of membranous organelles. A prokaryote does not have a discrete nucleus surrounded by a nuclear envelope. Prokaryotes reproduce mainly asexually by binary fission. When present, flagella are simple and solid; they do not have the 9 + 2 microtubule structure typical of eukaryotes. Two domains are made up of prokaryotes: Bacteria and Archaea. There are an estimated 1 trillion species of microbes on our planet. However, only about 14,000 prokaryote species have been classified.

DOMAIN BACTERIA

Very large, diverse group of prokaryotic organisms. Typically unicellular, but some form colonies or filaments. Mainly chemoheterotrophic, but some groups are photoautotrophic or photoheterotrophic, and some are chemoautotrophic. Bacteria are nonmotile or move by rotating flagella. Typically have peptidoglycan in their cell walls. Bacterial nomenclature and taxonomic practices are controversial and changing. See Table 25-3.

Proteobacteria Large, diverse group of gram-negative bacteria. Five subgroups are designated alpha, beta, gamma, delta, and epsilon. The alpha proteobacteria group includes *Rhizobium* and rickettsias. Beta proteobacteria include the bacterium that causes gonorrhea. Gamma proteobacteria include the enterobacteria, the group to which the intestinal bacterium *Escherichia coli* belongs, and the purple sulfur bacteria. The delta proteobacteria group includes the myxobacteria, and the epsilon bacteria include *Helicobacter*, which can cause peptic ulcers.

Gram-positive bacteria Diverse group; includes actinomycetes, lactic acid bacteria, mycobacteria, streptococci, staphylococci, and clostridia. Thick cell wall of peptidoglycan; many produce spores.

Mycoplasmas Lack cell walls. Extremely small bacteria bounded by plasma membrane. May have evolved from gram-positive bacteria.

Cyanobacteria Gram negative, photosynthetic.

Chlamydias Gram negative; lack peptidoglycan in their cell walls. Energy parasites dependent on host for ATP.

Spirochetes Gram negative; spiral-shaped bacteria with flexible cell walls.

DOMAIN ARCHAEA

Prokaryotes with unique cell membrane structure and cell walls lacking peptidoglycan. Also distinguished by their ribosomal RNA, lipid structure, and specific enzymes. About 225 named species. Based on molecular data, there are several clades, including **Crenarchaeota**, **Euryarchaeota**, **Korarchaeota**, **Nanoarchaeota**, and **Lokiarchaeota**. Two supergroups have been proposed: “TACK” and “Asgard.”

Archaea are common to most environments, including the human digestive tract. However, many archaea are adapted to extreme environments such as hot springs, sea vents, dry and salty seashores, boiling mud, and near ash-ejecting volcanoes (see Fig. 25-10). Three main types of archaea (not clades) based on their metabolism and ecology are:

Methanogens Anaerobes that produce methane gas from simple carbon compounds.

Extreme halophiles Inhabit saturated salt solutions.

Extreme thermophiles Some grow at 70°C or higher; others thrive above boiling point. Antarctic archaea live in very cold (1.8°C) environments.

EUKARYOTES

Eukaryotes are organisms that have a nucleus surrounded by a nuclear membrane. They have many other types of membrane-enclosed organelles as well.

DOMAIN EUKARYA

Domain Eukarya includes the protists, plants, fungi, and animals.

PROTISTS

Primarily unicellular or simple multicellular eukaryotic organisms that do not form tissues and that exhibit relatively little division of labor. Most modes of nutrition occur in this group. Life cycles may include both sexually and asexually reproducing phases and may be extremely complex, especially in parasitic forms. Locomotion is by cilia, flagella, amoeboid movement, or by other means; flagella and cilia have 9 + 2 structure. Many biologists recognize five supergroups: Excavates, Chromalveolates, Rhizarians, Archaeplastids, and Unikonts.

Excavates Unicellular protists that have deep, or excavated, oral (feeding) groove. Have atypical, greatly modified mitochondria or lack them. Many are endosymbionts. Currently include diplomonads, parabasilids, euglenoids, and trypanosomes.

Diplomonads Excavates with one or two nuclei, no functional mitochondria, no Golgi complex, and up to eight flagella.

Parabasilids Anaerobic, flagellated excavates that often live in animals. Include trichonymphs and trichomonads.

Euglenoids and trypanosomes Unicellular flagellates with crystalline rod in flagella; some free-living and some pathogenic. Many are heterotrophic, but some (about one-third) have plastids and are photosynthetic. At least 900 species.

Chromalveolates Diverse protists that may have originated as a result of secondary endosymbiosis in which an ancestral cell engulfed a red alga. Include alveolates (dinoflagellates, ciliates, and apicomplexans) and stramenopiles (water molds, diatoms, golden algae, and brown algae).

Alveolates Chromalveolates with alveoli, flattened vesicles located inside plasma membrane.

Dinoflagellates Unicellular (some colonial), photosynthetic, biflagellate. Cell walls composed of overlapping cell plates; contain cellulose. Contain chlorophylls *a* and *c* and carotenoids, including fucoxanthin. About 2000 to 4000 species.

Ciliates Unicellular protists that move by means of cilia. Reproduction is asexual by binary fission or sexual by conjugation. About 7200 species.

Apicomplexans Parasitic unicellular protists that lack specific structures for locomotion. At some stage in life cycle, they develop spores (small infective agents). Some pathogenic. About 3900 species.

Stramenopiles Diverse group; most have motile cells with two flagella, one with tiny, hairlike projections off shaft; no flagella in some. Include water molds, diatoms, golden algae, and brown algae.

Water molds Consist of branched, coenocytic mycelia. Cellulose and/or chitin in cell walls. Produce biflagellate

asexual spores. Sexual stage involves production of oospores. Some parasitic. About 700 species.

Diatoms Unicellular (some colonial), photosynthetic. Most nonmotile, but some move by gliding. Cell walls composed of silica rather than cellulose. Contain chlorophylls *a* and *c* and carotenoids, including fucoxanthin. At least 100,000 species estimated.

Golden algae Unicellular (some colonial), photosynthetic, biflagellate (some lack flagella). Cells covered by tiny scales of either silica or calcium carbonate. Contain chlorophylls *a* and *c* and carotenoids, including fucoxanthin. About 1000 species.

Brown algae Multicellular, often quite large (kelps). Photosynthetic; contain chlorophylls *a* and *c* and carotenoids, including fucoxanthin. Biflagellate reproductive cells. About 1500 species.

Rhizarians Amoeboid cells that often have tests (shells). Include forams and actinopods.

Foraminiferans (forams) Unicellular protists that produce calcareous tests (shells) with pores through which cytoplasmic projections extend, forming sticky net to entangle prey.

Actinopods Unicellular protists that produce axopods (long, filamentous cytoplasmic projections) that protrude through pores in their siliceous shells.

Archaeplastids Photosynthetic organisms with chloroplasts bounded by outer and inner membranes. This monophyletic group includes Plantae (land plants) and protists (red algae and green algae).

Red algae Most multicellular (some unicellular), mainly marine. Some (coralline algae) have bodies impregnated with calcium carbonate. No motile cells. Photosynthetic; contain chlorophyll *a*, carotenoids, phycocyanin, and phycoerythrin. About 5000 species.

Green algae Unicellular, colonial, and multicellular forms. Some motile and flagellate. Photosynthetic; contain chlorophylls *a* and *b* and carotenoids. About 17,000 species.

Unikonts Cells that have a single flagellum or are amoebas with no flagella. Have a triple-gene fusion that is lacking in other eukaryotes. Includes organisms currently classified in two kingdoms, Animalia and Fungi, and certain protists (amoebozoa and opisthokonts).

Amoebozoa Amoeboid protists that lack tests and move by means of lobose pseudopodia. Include amoebas, plasmodial slime molds, and cellular slime molds.

Amoebas Free-living and parasitic unicellular protists whose movement and capture of food are associated with pseudopodia.

Plasmodial slime molds Spend part of life cycle as thin, streaming, multinucleate plasmodium that creeps along on

decaying leaves or wood. Flagellate or amoeboid reproductive cells; form spores in sporangia. About 700 species.

Cellular slime molds Vegetative (nonreproductive) form is unicellular; move by pseudopods. Amoeba-like cells aggregate to form multicellular pseudoplasmodium that eventually develops into fruiting body that bears spores. About 50 species.

Opisthokonts Opisthokonts (Greek *opistho*, “rear,” and *kontos*, “pole”) have a single posterior flagellum in flagellate cells. Include animals, fungi, and choanoflagellates.

Choanoflagellates Have a single flagellum surrounded at its base by a collar of microvilli. Probably related to the common ancestor of animals.

KINGDOM PLANTAE

Multicellular eukaryotic organisms with differentiated tissues and organs. Cell walls contain cellulose. Cells frequently contain large vacuoles; photosynthetic pigments in plastids. Photosynthetic pigments are chlorophylls *a* and *b* and carotenoids. Nonmotile. Reproduce both asexually and sexually, with alternation of gametophyte (*n*) and sporophyte (*2n*) generations. Some biologists classify plants as Archaeplastids (along with red algae and green algae).

Phylum Bryophyta Mosses Nonvascular plants that lack xylem and phloem. Marked alternation of generations with dominant gametophyte generation. Motile sperm. Gametophytes generally form dense green mat consisting of individual plants. At least 9900 species.

Phylum Hepatophyta Liverworts Nonvascular plants that lack xylem and phloem. Marked alternation of generations with dominant gametophyte generation. Motile sperm. Gametophytes of certain species have flat, liverlike thallus; other species more mosslike in appearance. About 6000 species.

Phylum Anthocerophyta Hornworts Nonvascular plants that lack xylem and phloem. Marked alternation of generations with dominant gametophyte generation. Motile sperm. Gametophyte is small, flat, green thallus with scalloped edges. Spores produced on erect, hornlike stalk. About 100 species.

Phylum Pteridophyta Vascular plants with dominant sporophyte generation. Reproduce by spores. Motile sperm.

Ferns Generally homosporous. Gametophyte is free-living and photosynthetic. About 11,000 species.

Whisk ferns Homosporous. Sporophyte stem branches dichotomously; lacks true roots and leaves. Gametophyte is subterranean and nonphotosynthetic and forms mycorrhizal relationship with fungus. About 12 species.

Horsetails Homosporous. Sporophyte has hollow, jointed stems and reduced, scalelike leaves. Gametophyte is tiny photosynthetic plant. About 15 species.

Phylum Lycopodiophyta Club mosses Sporophyte plants are vascular with branching rhizomes and upright stems that bear microphylls. Although modern representatives are small, some extinct species were treelike. Some homosporous; others heterosporous. Motile sperm. About 1200 species.

Phylum Coniferophyta Conifers Heterosporous vascular plants with woody tissues (trees and shrubs) and needle-shaped or scalelike leaves. Most are evergreen. Seeds usually borne naked on surface of cone scales. Nutritive tissue in seed is haploid female gametophyte tissue. Nonmotile sperm. About 630 species.

Phylum Cycadophyta Cycads Heterosporous, vascular, dioecious plants that are small and shrubby or larger and palmlike. Produce naked seeds in conspicuous cones. Flagellate sperm. About 140 species.

Phylum Ginkgophyta Ginkgo Broadleaf deciduous trees that bear naked seeds directly on branches. Dioecious. Contain vascular tissues. Flagellate sperm. Ginkgo tree is only living representative. One species.

Phylum Gnetophyta Gnetophytes Woody shrubs, vines, or small trees that bear naked seeds in cones. Contain vascular tissues. Possess many features similar to flowering plants. About 70 species.

Phylum Anthophyta Flowering plants (angiosperms) Largest, most successful group of plants. Heterosporous; dominant sporophytes with extremely reduced gametophytes. Contain vascular tissues. Bear flowers, fruits, and seeds (enclosed in fruit; seeds contain endosperm as nutritive tissue). Double fertilization. More than 300,000 species.

KINGDOM FUNGI

Eukaryotic, mainly multicellular organisms with cell walls containing chitin. Heterotrophs that secrete digestive enzymes onto food source and then absorb predigested food. Most decomposers, but some parasites. Body form typically a mycelium. Cells typically haploid or dikaryotic, with brief diploid period following fertilization. Reproduce by means of spores, which may be produced sexually or asexually. No flagellate stages except in chytrids. Classified as opisthokonts (along with choanoflagellates and animals) because flagellate cells, where present, have a single posterior flagellum (Greek *opistho*, “rear,” and *kontos*, “pole”).

Phylum Chytridiomycota Chytridiomycetes (chytrids) Parasites and decomposers found mainly in fresh water. Motile cells (gametes and zoospores) contain single, posterior flagellum. Reproduce both sexually and asexually. About 1000 species.

Phylum Zygomycota Zygomycetes (molds) Important decomposers; some are insect parasites. Produce sexual resting spores called *zygospores* and nonmotile, haploid, asexual spores in

sporangium. Hyphae are coenocytic. Many are heterothallic (two mating types). About 1100 species.

Phylum Glomeromycota *Glomeromycetes* Symbionts that form intracellular mycorrhizal associations within roots of most trees and herbaceous plants. Reproduce asexually with large, multinucleate spores called *blastospores*. About 200 species.

Phylum Ascomycota *Ascomycetes, or sac fungi (yeasts, powdery mildews, molds, morels, truffles)* Important symbionts; 98% of lichen-forming fungi are ascomycetes; some form mycorrhizae. Sexual reproduction: form ascospores in sacs called *asci*. Asexual reproduction: produce spores called *conidia*, which pinch off from conidiophores. Hyphae usually have perforated septa. Dikaryotic stage. About 32,000 species.

Phylum Basidiomycota *Basidiomycetes, or club fungi (mushrooms, bracket fungi, puffballs)* Many form mycorrhizae with tree roots. Sexual reproduction: form basidiospores on basidium. Asexual reproduction uncommon. Heterothallic. Hyphae usually have perforated septa. Dikaryotic stage. More than 30,000 species.

KINGDOM ANIMALIA

Eukaryotic, multicellular heterotrophs with differentiated cells. In most animals, cells are organized to form tissues, tissues form organs, and tissues and organs form specialized organ systems that carry on specific functions. Most have a well-developed nervous system and respond adaptively to changes in their environment. Most are capable of locomotion during some time in their life cycle. Most are diploid and reproduce sexually; flagellate haploid sperm unites with large, nonmotile, haploid egg, forming diploid zygote that undergoes cleavage. Classified as opisthokonts (along with choanoflagellates and fungi) because flagellate cells, when present, have a single posterior flagellum (Greek *opistho*, “rear,” and *kontos*, “pole”).

Phylum Porifera *Sponges* Mainly marine; solitary or colonial. Body has many pores through which water circulates. Food is filtered from water by collar cells (choanocytes). Asexual reproduction by budding; external sexual reproduction in which sperm are released and swim to internal egg. Larva is motile. About 9,000 species.

Phylum Cnidaria *Medusozoans (hydras, jellyfish); anthozoans (sea anemones, corals)* Marine, with a few freshwater species; solitary or colonial; polyp and medusa forms. Radial symmetry. Tentacles surrounding mouth. Stinging cells (cnidocytes) contain stinging structures called *nematocysts*. Planula larva. More than 10,000 species.

Phylum Ctenophora *Comb jellies* Marine; free-swimming. Biradial symmetry. Two tentacles and eight longitudinal rows of cilia resembling combs; animal moves by means of these bands of cilia. More than 200 species.

Protostomes: Lophotrochozoa

Most are true coelomates (characterized by a body cavity completely lined with mesoderm). Spiral, determinate cleavage; mouth typically develops from blastopore. There are two branches of protostomes: Lophotrochozoa and Ecdysozoa. The Lophotrochozoa include the platyhelminths, nemertean (ribbon worms), mollusks, annelids, the lophophorate phyla, and the rotifers. The name *Lophotrochozoa* comes from two characteristics of some animals in this clade: the lophophore, a ciliated ring of tentacles surrounding the mouth in three small groups of animals, and the trochophore larva that characterizes its two major groups: the mollusks and annelids.

Phylum Platyhelminthes *Flatworms* Acoelomate (no body cavity); region between body wall and internal organs filled with tissue. Planarians are free-living; Parasitic flatworms include flukes and tapeworms. Flatworm body dorsoventrally flattened; cephalization; three tissue layers. Simple nervous system with ganglia in head region. Excretory organs are protonephridia with flame cells. About 20,000 species.

Phylum Nemertea *Ribbon worms (also called proboscis worms)* Long, dorsoventrally flattened body with complex proboscis used for defense and for capturing prey. Functionally acoelomate but have small true coelom in proboscis. Definite organ systems. Complete digestive tract. Circulatory system with blood. About 1200 species.

Phylum Mollusca *Chitons; gastropods (snails, slugs); bivalves (clams, oysters); cephalopods (squids, octopuses)* Unsegmented, soft-bodied true coelomate animals; many covered by dorsal shell. Have ventral, muscular foot. Most organs located above foot in visceral mass. Shell-secreting mantle covers visceral mass and forms mantle cavity, which contains gills. Trochophore and/or veliger larva. More than 100,000 species.

Phylum Annelida *Segmented worms: errantians (marine worms); sedentarians (earthworms, leeches)* True coelomates; both body wall and internal organs are segmented. Body segments separated by septa. Some have nonjointed appendages. Setae used in locomotion. Closed circulatory system; metanephridia; specialized regions of digestive tract. Trochophore larva. More than 17,000 species.

Phylum Brachiopoda *Lamp shells* One of lophophorate phyla. Marine; body enclosed between two shells. About 325 species.

Phylum Phoronida One of lophophorate phyla. Tube-dwelling marine worms. About 20 species.

Phylum Bryozoa One of lophophorate phyla. Mainly marine; sessile colonies produced by asexual budding. About 4500 species.

Phylum Rotifera *Wheel animals* Aquatic, microscopic. Anterior end has ciliated crown that looks like wheel when cilia

beat. Posterior end tapers to foot. Characterized by pseudo-coelom (body cavity not completely lined with mesoderm). Constant number of cells in adult. About 2000 species.

Protostomes: Ecdysozoa

Animals in this group of protostomes characterized by ecdysis (molting).

Phylum Nematoda *Roundworms: ascaris, hookworms, pinworms* Slender, elongated, cylindrical worms; covered with cuticle. Characterized by pseudocoelom (body cavity not completely lined with mesoderm). Free-living and parasitic forms. More than 25,000 species.

Phylum Arthropoda *Myriapods (centipedes, millipedes); chelicerates (horseshoe crabs, spiders, ticks); pancrustaceans: crustaceans (lobsters, crabs, shrimp) and insects* Segmented animals with paired, jointed appendages and hard exoskeleton made of chitin. Open circulatory system with dorsal heart. Hemocoel occupies most of body cavity, and coelom is reduced. More than 1 million species have been described.

Deuterostomes

True coelomates with radial, indeterminate cleavage. Blastopore develops into anus, and mouth forms from second opening. At some time in their life cycle most deuterostomes (except echinoderms) develop pharyngeal slits, openings that connect the pharynx with the outside environment.

Phylum Echinodermata *Sea stars, sea urchins, sand dollars, sea cucumbers* Marine. Pentaradial symmetry as adults; bilateral symmetry as larvae. Endoskeleton of small, calcareous plates. Water vascular system; tube feet for locomotion. About 7000 species.

Phylum Hemichordata *Acorn worms* Marine with ring of cilia around mouth. Anterior muscular proboscis is connected by collar region to long, wormlike body. Larval form resembles echinoderm larva. About 140 species.

Phylum Chordata *Subphylum Urochordata (tunicates), subphylum Cephalochordata (lancelets), subphylum Vertebrata (fishes, amphibians, non-avian reptiles, avian reptiles [birds], mammals)* Notochord; dorsal, tubular nerve cord; postanal tail; and endostyle. About 70,000 species.

Understanding Biological Terms

Your task of mastering new terms will be greatly simplified if you learn to dissect each new word. Many terms can be divided into a prefix, the part of the word that precedes the main root; the word root itself; and often a suffix, a word ending that may add to or modify the meaning of the root. As you progress in your study of biology, you will learn to recognize the more common prefixes, word roots, and suffixes. Such recognition will help you analyze new terms so that you can more readily determine their meaning and will help you remember them.

Prefixes

a-, ab- from, away, apart (*abduct*, move away from the midline of the body)

a-, an-, un- less, lack, not (*asymmetrical*, not symmetrical)

ad- (also **af-, ag-, an-, ap-**) to, toward (*adduct*, move toward the midline of the body)

allo- different (*allometric growth*, different rates of growth for different parts of the body during development)

ambi- both sides (*ambidextrous*, able to use either hand)

andro- a man (*androecium*, the male portion of a flower)

anis- unequal (*anisogamy*, sexual reproduction in which the gametes are of unequal sizes)

ante- forward, before (*anteflexion*, bending forward)

anti- against (*antibody*, proteins that have the capacity to react against foreign substances in the body)

auto- self (*autotroph*, organism that manufactures its own food)

bi- two (*biennial*, a plant that takes two years to complete its life cycle)

bio- life (*biology*, the study of life)

circum-, circ- around (*circumcision*, a cutting around)

co-, con- with, together (*congenital*, existing with or before birth)

contra- against (*contraception*, against conception)

cyt- cell (*cytology*, the study of cells)

di- two (*disaccharide*, a compound made of two sugar molecules chemically combined)

dis- apart (*dissect*, cut apart)

ecto- outside (*ectoderm*, outer layer of cells)

end-, endo- within, inner (*endoplasmic reticulum*, a network of membranes found within the cytoplasm)

epi- on, upon (*epidermis*, upon the dermis)

ex-, e-, ef- out from, out of (*extension*, a straightening out)

extra- outside, beyond (*extraembryonic membrane*, a membrane that encircles and protects the embryo)

gravi- heavy (*gravitropism*, growth of a plant in response to gravity)

hemi- half (*cerebral hemisphere*, lateral half of the cerebrum)

hetero- other, different (*heterozygous*, having unlike members of a gene pair)

homeo- unchanging, steady (*homeostasis*, reaching a steady state)

homo-, hom- same (*homologous*, corresponding in structure; *homozygous*, having identical members of a gene pair)

hyper- excessive, above normal (*hypersecretion*, excessive secretion)

hypo- under, below, deficient (*hypotonic*, a solution whose osmotic pressure is less than that of a solution with which it is compared)

in-, im- not (*incomplete flower*, a flower that does not have one or more of the four main parts)

inter- between, among (*interstitial*, situated between parts)

intra- within (*intracellular*, within the cell)

iso- equal, like (*isotonic*, equal osmotic pressure)

macro- large (*macronucleus*, a large, polyploid nucleus found in ciliates)

mal- bad, abnormal (*malnutrition*, poor nutrition)

mega- large, great (*megakaryocyte*, giant cell of bone marrow)

meso- middle (*mesoderm*, middle tissue layer of the animal embryo)

meta- after, beyond (*metaphase*, the stage of mitosis after prophase)

micro- small (*microscope*, instrument for viewing small objects)

mono- one (*monocot*, a group of flowering plants with one cotyledon, or seed leaf, in the seed)

oligo- small, few, scant (*oligotrophic lake*, a lake deficient in nutrients and organisms)

oo- egg (*oocyte*, cell that gives rise to an egg cell)

paedo- a child (*paedomorphosis*, the preservation of a juvenile characteristic in an adult)

para- near, beside, beyond (*paracentral*, near the center)

peri- around (*pericardial membrane*, membrane that surrounds the heart)

photo- light (*phototropism*, growth of a plant in response to the direction of light)

poly- many, much, multiple, complex (*polysaccharide*, a carbohydrate composed of many simple sugars)

post- after, behind (*postnatal*, after birth)

pre- before (*prenatal*, before birth)

pseudo- false (*pseudopod*, a temporary protrusion of a cell, i.e., "false foot")

retro- backward (*retroperitoneal*, located behind the peritoneum)

semi- half (*semilunar*, half-moon)

sub- under (*subcutaneous tissue*, tissue immediately under the skin)

super-, supra- above (*suprarenal*, above the kidney)

sym- with, together (*sympatric speciation*, evolution of a new species within the same geographic region as the parent species)

syn- with, together (*syndrome*, a group of symptoms that occur together and characterize a disease)

trans- across, beyond (*transport*, carry across)

Suffixes

-able, -ible able (*viable*, able to live)

-ad used in anatomy to form adverbs of direction (*cephalad*, toward the head)

-asis, -asia, -esis condition or state of (*euthanasia*, state of "good death")

-cide kill, destroy (*biocide*, substance that kills living things)

-emia condition of blood (*anemia*, a blood condition in which there is a lack of red blood cells)

-gen something produced or generated or something that produces or generates (*pathogen*, an organism that produces disease)

-gram record, write (*electrocardiogram*, a record of the electrical activity of the heart)

-graph record, write (*electrocardiograph*, an instrument for recording the electrical activity of the heart)

-ic adjective-forming suffix that means of or pertaining to (*ophthalmic*, of or pertaining to the eye)
-itis inflammation of (*appendicitis*, inflammation of the appendix)
-logy study or science of (*cytology*, study of cells)
-oid like, in the form of (*thyroid*, in the form of a shield, referring to the shape of the thyroid gland)
-oma tumor (*carcinoma*, a malignant tumor)
-osis indicates disease (*psychosis*, a mental disease)
-pathy disease (*dermatopathy*, disease of the skin)
-phyll leaf (*mesophyll*, the middle tissue of the leaf)
-scope instrument for viewing or observing (*microscope*, instrument for viewing small objects)

Some Common Word Roots

abscis cut off (*abscission*, the falling off of leaves or other plant parts)
angi, angio vessel (*angiosperm*, a plant that produces seeds enclosed within a fruit or “vessel”)
apic tip, apex (*apical meristem*, area of cell division located at the tips of plant stems and roots)
arthr joint (*arthropods*, invertebrate animals with jointed legs and segmented bodies)
aux grow, enlarge (*auxin*, a plant hormone involved in growth and development)
blast a formative cell, germ layer (*osteoblast*, cell that gives rise to bone cells)
brachi arm (*brachial artery*, blood vessel that supplies the arm)
bry grow, swell (*embryo*, an organism in the early stages of development)
cardi heart (*cardiac*, pertaining to the heart)
carot carrot (*carotene*, a yellow, orange, or red pigment in plants)
cephal head (*cephalad*, toward the head)
cerebr brain (*cerebral*, pertaining to the brain)
cervic, cervix neck (*cervical*, pertaining to the neck)
chlor green (*chlorophyll*, a green pigment found in plants)
chondr cartilage (*chondrocyte*, a cartilage cell)
chrom color (*chromosome*, deeply staining body in nucleus)
cili small hair (*cilium*, a short, fine cytoplasmic hair projecting from the surface of a cell)
coleo a sheath (*coleoptile*, a protective sheath that encircles the stem in grass seedlings)
conjug joined (*conjugation*, a sexual phenomenon in certain protists)
cran skull (*cranial*, pertaining to the skull)
decid falling off (*deciduous*, a plant that sheds its leaves at the end of the growing season)
dehis split (*dehiscent fruit*, a fruit that splits open at maturity)
derm skin (*dermatology*, study of the skin)
ecol dwelling, house (*ecology*, the study of organisms in relation to their environment, i.e., “their house”)
enter intestine (*enterobacteria*, a group of bacteria that includes species that inhabit the intestines of humans and other animals)
evol to unroll (*evolution*, descent with modification, gradual directional change)
fil a thread (*filament*, the thin stalk of the stamen in flowers)
gamet a wife or husband (*gametangium*, the part of a plant, protist, or fungus that produces reproductive cells)
gastr stomach (*gastrointestinal tract*, the digestive tract)

glyc, glyco sweet, sugar (*glycogen*, storage form of glucose)
gon seed (*gonad*, an organ that produces gametes)
gutt a drop (*guttation*, loss of water as liquid “drops” from plants)
gymn naked (*gymnosperm*, a plant that produces seeds that are not enclosed with a fruit, i.e., “naked”)
hem blood (*hemoglobin*, the pigment of red blood cells)
hepat liver (*hepatic*, of or pertaining to the liver)
hist tissue (*histology*, study of tissues)
hydr water (*hydrolysis*, a breakdown reaction involving water)
leuk white (*leukocyte*, white blood cell)
menin membrane (*meninges*, the three membranes that envelop the brain and spinal cord)
morph form (*morphogenesis*, development of body form)
my, myo muscle (*myocardium*, muscle layer of the heart)
myc a fungus (*mycelium*, the vegetative body of a fungus)
neph kidney (*nephron*, microscopic unit of the kidney)
neur, nerv nerve (*neuromuscular*, involving both the nerves and muscles)
occiput back part of the head (*occipital*, back region of the head)
ost bone (*osteology*, study of bones)
path disease (*pathologist*, one who studies disease processes)
ped, pod foot (*bipedal*, walking on two feet)
pell skin (*pellicle*, a flexible covering over the body of certain protists)
phag eat (*phagocytosis*, process by which certain cells ingest particles and foreign matter)
phil love (*hydrophilic*, a substance that attracts, i.e., “loves,” water)
phloe bark of a tree (*phloem*, food-conducting tissue in plants that corresponds to bark in woody plants)
phyt plant (*xerophyte*, a plant adapted to xeric, or dry, conditions)
plankt wandering (*plankton*, microscopic aquatic protists that float or drift passively)
rhiz root (*rhizome*, a horizontal, underground stem that superficially resembles a root)
scler hard (*sclerenchyma*, cells that provide strength and support in the plant body)
sipho a tube (*siphonous*, a type of tubular body form found in certain algae)
som body (*chromosome*, deeply staining body in the nucleus)
sor heap (*sorus*, a cluster or “heap” of sporangia in a fern)
spor seed (*spore*, a reproductive cell that gives rise to individual offspring in plants, protists, and fungi)
stom a mouth (*stoma*, a small pore, i.e., “mouth,” in the epidermis of plants)
thigm a touch (*thigmotropism*, plant growth in response to touch)
thromb clot (*thrombus*, a clot within a blood vessel)
troph nourishment (*heterotroph*, an organism that must depend on other organisms for its nourishment)
tropi turn (*thigmotropism*, growth of a plant in response to contact with a solid object, such as a tendril “turning” or wrapping around a wire fence)
visc pertaining to an internal organ or body cavity (*viscera*, internal organs)
xanth yellow (*xanthophyll*, a yellowish pigment found in plants)
xyl wood (*xylem*, water-conducting tissue in plant, the “wood” of woody plants)
zoo an animal (*zoology*, the science of animals)

Abbreviations

The biological sciences use a great many abbreviations and with good reason. Many technical terms in biology and biological chemistry are both long and difficult to pronounce. When confronted with something like NADPH or EPSP, it can be difficult for beginners to understand the reference. Here, for your ready reference, are some of the common abbreviations used in biology.

A adenine
Ab antibody
ABA abscisic acid
ABC transporters ATP-binding cassette transporters
ABP androgen-binding protein
ACE a key enzyme responsible for synthesis of angiotensin II, a hormone that constricts arteries, increasing blood pressure
ACh acetylcholine
ACTH adrenocorticotrophic hormone
AD Alzheimer's disease
ADH antidiuretic hormone
ADP adenosine diphosphate
AIDS acquired immunodeficiency syndrome
AMP adenosine monophosphate
amu atomic mass unit (dalton)
ANP atrial natriuretic peptide
APC anaphase-promoting complex *or* antigen-presenting cell
ATP adenosine triphosphate
AV node *or* **valve** atrioventricular node *or* valve (of heart)
B lymphocyte *or* **B cell** lymphocyte responsible for antibody-mediated immunity
BH brain hormone (of insects)
BMI body mass index
BMR basal metabolic rate
BP blood pressure
BR brassinosteroid
bya billion years ago
C cytosine
C₃ three-carbon pathway for carbon fixation (Calvin cycle)
C₄ four-carbon pathway for carbon fixation
Ca Cancer
cal calories
CAM crassulacean acid metabolism
cAMP cyclic adenosine monophosphate
CAP catabolite activator protein
CBC complete blood count
CCK cholecystokinin
CD4 T cell T helper cell (T_H); T cell with a surface marker designated CD4
CD8 T cell T cell with a surface marker designated CD8; includes T cytotoxic cells (T_C)
Cdk cyclin-dependent protein kinase
cDNA complementary deoxyribonucleic acid
CFCs chlorofluorocarbons
CFTR cystic fibrosis transmembrane conductance regulator
cGMP cyclic guanosine monophosphate
CITES Convention on International Trade in Endangered Species of Wild Flora and Fauna
CNS central nervous system
CNVs copy number variations
CO cardiac output
CoA coenzyme A
COPD chronic obstructive pulmonary disease

CP creatine phosphate
CPR cardiopulmonary resuscitation
CREB cyclic AMP response element binding protein
CRF corticotropin releasing factor
CRISPR clusters of regularly interspersed short palindromic repeats
CSF cerebrospinal fluid
CVA cardiovascular accident
CVS cardiovascular system *or* chorionic villus sampling
DAG diacylglycerol
DNA deoxyribonucleic acid
DOC dissolved organic carbon
E_A activation energy (of an enzyme)
ECG electrocardiogram
ECM extracellular matrix
EEG electroencephalogram
EKG electrocardiogram
EM electron microscope *or* micrograph
ENSO El Niño–Southern Oscillation
EPSP excitatory postsynaptic potential (of a neuron)
ER endoplasmic reticulum
ERK extracellular signal-regulated kinases
ES cells embryonic stem cells
F₁ first filial generation
F₂ second filial generation
Fab portion the part of an antibody that binds to an antigen
Factor VIII blood-clotting factor (absent in certain hemophiliacs)
FAD/FADH₂ flavin adenine dinucleotide (oxidized and reduced forms, respectively)
FAP fixed action pattern
F_c portion the part of an antibody that interacts with cells of the immune system
FISH fluorescent in situ hybridization
FSH follicle-stimulating hormone
G free energy
G guanine
G protein cell-signaling molecule that requires GTP
G₁ phase first gap phase (of the cell cycle)
G₂ phase second gap phase (of the cell cycle)
G3P glyceraldehyde-3-phosphate
GA gibberellin
GAA Global Amphibian Assessment (by World Conservation Union)
GABA gamma-aminobutyric acid
GFP green fluorescent protein
GH growth hormone (somatotropin)
GHIH growth hormone-inhibiting hormone
GHRH growth hormone-releasing hormone
G_i a G protein that inhibits adenylyl cyclase
GINA Genetic Information Nondiscrimination Act
GIP glucose-dependent insulinotropic peptide
GnRH gonadotropin-releasing hormone
GPP gross primary productivity
G_s a G protein that stimulates adenylyl cyclase
GTP guanosine triphosphate
GWA genome-wide association
H enthalpy
Hb hemoglobin
HBEF Hubbard Brook Experimental Forest
HBO₂ oxyhemoglobin
HCFCs hydrochlorofluorocarbons
hCG human chorionic gonadotropin
HD Huntington disease
HDL high-density lipoprotein

HFCs hydrofluorocarbons
HGH human growth hormone
HIV human immunodeficiency virus
HLA human leukocyte antigen
HPV human papillomavirus
IAA indole acetic acid (natural auxin)
IBD inflammatory bowel disease, for example, Crohn's disease and ulcerative colitis
Ig immunoglobulin, as in IgA, IgG, etc.
IGF insulin-like growth factor
IP₃ inositol trisphosphate
IPCC United Nations Intergovernmental Panel on Climate Change
iPSCs induced pluripotent stem cells
IPSP inhibitory postsynaptic potential (of a neuron)
IU international units
IUCN World Conservation Union
IUD intrauterine device
IVF in vitro fertilization
J joules
JH juvenile hormone (of insects)
kb kilobase
kcal kilocalories
kJ kilojoules
LDH lactate dehydrogenase enzyme
LDL low-density lipoprotein
LH luteinizing hormone
LM light microscope or micrograph
lncRNA long non-coding RNA
LSD lysergic acid diethylamide
LTP long-term potentiation
LUCA last universal common ancestor
MAO monoamine oxidase
MAP mitogen-activated protein
MAPs microtubule-associated proteins
MH molting hormone (ecdysone)
MHC major histocompatibility complex
MI myocardial infarction
miRNA microRNA
MRI magnetic resonance imaging
mRNA messenger RNA
MSH melanocyte-stimulating hormone
mtDNA mitochondrial DNA
MTOC microtubule organizing center
MVP minimum viable population
mya million years ago
9 + 2 structure cilium or flagellum (of a eukaryote)
9 × 3 structure centriole or basal body (of a eukaryote)
n*, 2*n the chromosome number of a gamete and of a zygote, respectively
NAD⁺/NADH nicotinamide adenine dinucleotide (oxidized and reduced forms, respectively)
NADP⁺/NADPH nicotinamide adenine dinucleotide phosphate (oxidized and reduced forms, respectively)
NAG *N*-acetyl glucosamine
NK cell natural killer cell
NLS nuclear localization signal
NMDA *N*-methyl-D aspartate (an artificial ligand)
NO nitric oxide
NPP net primary productivity
NPY neuropeptide Y
NSF National Science Foundation
P generation parental generation
P53 a tumor suppressor gene
P680 reaction center of photosystem II
P700 reaction center of photosystem I
PABA para-aminobenzoic acid
PAMPs pathogen-associated molecular patterns
PCR polymerase chain reaction

PEP phosphoenolpyruvate
Pfr phytochrome (form that absorbs far-red light)
PGA phosphoglycerate
PGD preimplantation genetic diagnosis
PID pelvic inflammatory disease
piRNA piwi-associated RNA
PKU phenylketonuria
PNS peripheral nervous system
Pr phytochrome (form that absorbs red light)
pre-mRNA precursor messenger RNA (in eukaryotes)
PRR pattern recognition receptor
PTH parathyroid hormone
PTSD post-traumatic stress disorder
qPCR quantitative polymerase chain reaction
r growth rate of a population
RA rheumatoid arthritis
RAO recent African origin
RAS reticular activating system
RBC red blood cell (erythrocyte)
REM sleep rapid-eye-movement sleep
RFLP restriction fragment length polymorphism
***r*_{max}** intrinsic rate of increase (of a population)
RNA ribonucleic acid
RNAi RNA interference
RNA-seq RNA sequencing
rRNA ribosomal RNA
RT-PCR reverse transcriptase polymerase chain reaction
rubisco ribulose biphosphate carboxylase/oxygenase
RuBP ribulose biphosphate
S entropy
S phase DNA synthetic phase (of the cell cycle)
SA node sinoatrial node (of heart)
SAR systemic acquired resistance (in plants)
SCID severe combined immunodeficiency
SEM scanning electron microscope or micrograph
siRNA small interfering RNA
snoRNA small nucleolar RNA
SNPs single nucleotide polymorphisms (“snips”)
snRNA small nuclear RNA
snRNPs small nuclear ribonucleoprotein complexes (“snurps”)
SRP signal-recognition particle
SSB protein single-strand binding protein
ssp subspecies
STD sexually transmitted disease
STI sexually transmitted infection
STR short tandem repeat
T thymine
T₃ triiodothyronine
T₄ thyroxine
T lymphocyte or **T cell** lymphocyte responsible for cell-mediated immunity
T_C lymphocyte T cytotoxic cell (CD8 T cell)
T_H lymphocyte T helper cell (CD4 T cell)
TATA box base sequence in eukaryotic promoter
TCA cycle tricarboxylic acid cycle (citric acid cycle, Krebs cycle)
TCR T-cell receptor
TEM transmission electron microscope or micrograph
Tm tubular transport maximum
TNF tumor necrosis factor
TPA tissue plasminogen activator
TRH thyroid-releasing hormone
tRNA transfer RNA
TSH thyroid-stimulating hormone
U uracil
UV light ultraviolet light
WBC white blood cell (leukocyte)

Answers

Chapter 1

Checkpoint

1.1 • Information transmission, energy transfer, and evolution are considered basic to life because organisms must be able to send and receive information within their own bodies and with other organisms and their environment; organisms must be able to transfer energy from one form to another to perform life functions; populations of organisms must change over time, or evolve, to survive as their environment changes. • Consumers are dependent on producers for food and energy. Producers and consumers are dependent on decomposers for recycling nutrients. Organisms are interdependent for maintaining the needed balance of gases in the atmosphere. **1.2** • Living organisms differ from a rock because they are characterized by cellular organization, growth and development, self-regulated metabolism, the ability to respond to stimuli, reproduction, and adaptation to environmental change. • If an organism's homeostatic mechanisms failed, the organism could not maintain metabolic processes and it would die. **1.3** • The levels of organization within an organism are the chemical level (atoms and molecules), cells, tissues, organs, and organ systems. • Ecosystems include all of the other categories; because they are the most complex, they interact with the most other biological systems. **1.4** • DNA contains the genetic information coded in sequences of nucleotides. This information determines the structure and function of each individual and is transmitted from one generation to the next. • A nervous system transmits information through electrical impulses and chemical compounds, called neurotransmitters. **1.5** • A forest ecosystem would include producers (flowering plants, bushes, trees), primary consumers (grasshoppers, rabbits, worms), secondary consumers (birds, coyote, snakes), and decomposers (bacteria, fungi, archaea). • Consumers depend on producers to provide energy captured from the sun by photosynthesis and stored as carbohydrates. Consumers depend on decomposers to break down complex compounds, releasing nutrients and elements for reuse by producers and consumers. **1.6** • *Python* is the genus name for the African rock python. • The tree showing the major forms of life may be modified as scientists obtain additional data about evolutionary relationships. • The

sharp claws and teeth of tigers would have been an evolutionary advantage (improved predation and defensive ability). Tigers with the sharpest claws and teeth were more likely to survive and pass their survival genes on to their offspring. With time these traits became an important adaptation in the tiger population. **1.7** • A good hypothesis is reasonably consistent with well-established facts, generates predictions that can be tested, and yields test results that are repeatable by independent researchers. A good hypothesis is also falsifiable; that is, it can be tested and if not true, it can be proved false through testing. • A controlled experiment consists of an experimental group and a control group, which are treated identically except for a variable treatment of the experimental group. • Systems biology depends on information generated by the reductionist approach to yield basic information about components of biological systems.

Figure Questions

FIG. 1-9 Smog and discharge from factories, utilities, and automobiles can reduce sunshine over broad areas, decreasing photosynthesis. This results in slowed growth and possible death in plants and algae. This situation would result in less food, or available energy, for animals and other organisms. Gases released into the atmosphere also cause acidified precipitation, which damages leaves of producers. Increased carbon dioxide levels further increase climate change. **FIG. 1-10** The mushroom would first be classified into a domain (Eukarya), then kingdom (Fungi). Physical and molecular information would help to determine phylum, class, order, family, genus, and species of the mushroom. **FIG. 1-11** The protists do not share enough common characteristics to be classified as a kingdom. They have been placed in five “super-groups” based on their commonalities to better reflect how they are related by evolution. **FIG. 1-16** The cell may be able to carry out life processes under the direction of the donor nucleus. **FIG. 1-17** Results from the repeated experiment might be similar but may not be identical to the result from the previous experiment.

Test Your Understanding

1. c 2. e 3. c 4. d 5. b 6. c 7. e 8. d

9. See also Fig. 1-11.

10. Failure of the homeostatic mechanism could cause the organism to die. Further explanation relies on a logical description and discussion of the homeostatic mechanism selected for example. 11. A good hypothesis is reasonably consistent with well-established facts, generates predictions that can be tested, yields test results that are repeatable by independent researchers, and is falsifiable, or can be proved false through testing. Examples here will vary. 12. Any answer is acceptable if logically presented and defended. 13. Reductionists study the simplest components of biological processes to understand the whole, while systems biology researchers take the large amounts of reductionist-derived data and do computer analyses to understand the big picture of how biological systems function. Systems biology depends on reductionism because it relies on information generated by the reductionist approach to yield basic information about components and large data sets. The systems approach is more likely to consider emergent properties. 14. The second graph shows the number of chimpanzees who successfully employed learned tool use and retained the knowledge, or remembered, after two months. As time passes, a learned skill may be forgotten. 15. Evolution depends on transfer of information because organisms must be able to respond to changes in their environment in order for the population to adapt. Transfer of information depends on evolution because as an organism adapts to the environment, communication may change. 16. Any response that is defended by logical argument is acceptable. 17. Any subjective response that is defended by logical argument is acceptable.

Chapter 2

Checkpoint

2.1 • All atoms of an element have the same atomic number, corresponding to the number of protons in the nucleus. Different isotopes of the same element have different atomic masses, depending on their number of neutrons. • A radioisotope is an unstable isotope of an element that can decay, releasing a radioactive particle, such as a β particle. Radioisotopes are used in research to label biological molecules used to trace biochemical pathways and follow the transport of molecules in cells and tissues. • Electrons occupying different orbitals of the same electron shell are at the same principal energy level (i.e., have similar energies). **2.2** • A radioisotope can substitute for a nonradioactive atom of the same element because both isotopes have the same chemical characteristics. • Structural formulas contain the most information because they illustrate the structural arrangement of atoms in the compound, as well as their types and numbers. • One gram of hydrogen atoms would contain one mole, or 6.02×10^{23} particles of hydrogen atoms. Two grams of hydrogen molecules (one mole of H_2 would also contain 6.02×10^{23} particles. **2.3** • A chemical compound consists of atoms of two or more different elements combined in a fixed ratio. Not all compounds are made up of molecules. For example, sodium chloride is not a molecule because the sodium and chloride atoms are not joined by covalent bonds. • An atom or molecule can become an anion by gaining one or more electrons; a molecule can also become an anion by losing one or

more protons. An atom or molecule can become a cation by losing one or more electrons; a molecule can also become a cation by gaining one or more protons. • Ionic bonds are formed by an attraction between the positive charge of a cation and the negative charge of an anion. Covalent bonds are formed between atoms that share electrons. • Weak forces, such as hydrogen bonds and van der Waals interactions, can produce strong forces when large numbers of these bonds occur over short distances between regions of molecules. 2.4 • In redox reactions, energy is transferred in the form of electrons. 2.5 • Water molecules are formed by polar covalent bonds between oxygen and two hydrogen atoms. The region around the oxygen atom is slightly negative and the regions around the hydrogen atoms are slightly positive, allowing hydrogen bonds to form between the oxygen atom of one water molecule and a hydrogen atom of another water molecule. • Hydrogen bonding is responsible for water's high specific heat, which affects the freezing and boiling points of water. Hydrogen bonding also affects the spacing of water molecules in ice, making ice less dense and allowing ice to float on liquid water. The high water content of organisms helps them maintain relatively constant internal temperatures. The high heat of vaporization of water also allows organisms to dissipate heat through evaporative cooling. • Weak forces such as hydrogen bonds have collective strength when many work together. 2.6 • A solution with a $[H^+]$ of 10^{-2} has a pH of 2.0. Its hydroxide ion concentration is 10^{-12} . The solution is strongly acidic. Its $[H^+]$ is one-tenth that of a solution with a pH of 1.0. • Adding a reactant or removing a product would shift the system to the right, resulting in the formation of more product. Adding a product or removing a reactant would shift the system to the left, resulting in the formation of more reactant. • Buffers prevent excessive acidity or alkalinity from occurring in organisms, helping to maintain cellular and extracellular environments within a narrow range of pH. Strong acids or bases cannot work as buffers because there are few undissociated molecules present relative to the dissociated components of the system. This prevents a dynamic equilibrium from forming, which can allow associated or dissociated components to be produced. • Electrolytes, such as acids, bases, and salts, dissociate to form anions and cations in solution, allowing the solution to conduct electric current.

Figure Questions

FIG. 2-1 Examine the Bohr model for oxygen (atomic number 8) in Figure 2-1. A Bohr model for fluorine would have an additional electron in its valence shell.

FIG. 2-5 An N_2 molecule has 2 electrons in each inner shell and 5 electrons in each valence shell. There are 3 pairs of electrons bonded between the two atoms.

Test Your Understanding

1. c 2. e 3. a 4. b 5. c 6. d 7. a 8. a 9. d 10. e 11. e 12. e 13. Refer to Figure 2-1 to construct your diagram. Element A would be expected to donate electrons. Element B would most likely share electrons. Element C would be expected to accept electrons.

14. HCl is the reactant. H^+ and Cl^- are the products. The expression indicates that this is an irreversible reaction. HCl is a strong acid and could not be used as a buffer because there would be very little undissociated HCl remaining after the reaction. 15. You should not immerse your hand. The solution has a pH of 12, which is strongly basic. 16. If hydrogen bonds were stronger, the freezing point of water would be higher, its boiling point would be higher, and it would have a higher specific heat and heat of vaporization. If hydrogen bonds were weaker, these properties would be lower than for existing water. 17. Water is the most fundamental indicator because its unique properties make it unlikely that life could evolve in its absence.

Chapter 3

Checkpoint

3.1 • Carbon-carbon bonds can produce a wide variety of 3-D molecular shapes because the four possible covalent bonds do not form in a single plane. Carbon-carbon bonds can consist of single, double, or triple bonds that are strong and not easily broken. These bonds can form unbranched or branched chains as well as rings that can be joined, forming complex 3-D structures.

Structural isomers

trans

cis

Geometric isomers

Enantiomers

See also Figure 3-3 for examples of different types of isomers. Isomers with the same molecular formula have different physical and chemical properties. Cells can distinguish between isomers and usually only one will be biologically active.

See also Table 3-1 for the structures and properties of functional groups. • Nonpolar groups lack distinct charged regions and do not interact readily with water. Polar, acidic, and basic groups are hydrophilic. They have charged regions that associate with polar water molecules.

See also Figure 3-5 for an illustration of how water molecules participate in condensation and hydrolysis reactions.

3.2 •

Starch and glycogen

Cellulose and chitin

See also Figures 3-9 and 3-10. Hydrogen bonding between the hydroxyl groups of the sugar units occurs in polysaccharides. These bonds form within a single molecule of a storage polysaccharide, resulting in a helical structure. The hydrogen bonds in structural polysaccharides form between adjacent molecules, resulting in bundles of fibers. 3.3 • Saturated fatty acids contain flexible, unbranched hydrocarbon chains. Adjacent saturated fatty acids can align with each other, and associate by van der Waals interactions along the length of the chains. This makes them more solid at a given temperature by limiting the motions of the chains. Unsaturated fatty acids contain double bonds that produce bends in the chains, preventing them from aligning closely with adjacent chains, reducing the number of van der Waals interactions. *Cis* fatty acids are more liquid than saturated fatty acids at a given temperature. *Trans* fatty acids contain double bonds that do not produce a bend in the chain. These mimic the properties of saturated fatty acids and are more solid at a given temperature than *cis* fatty acids. • Phospholipids are amphipathic molecules. These molecules can form a bilayer in which their hydrophobic fatty acid chains associate in the center of the two layers and the hydrophilic head groups interact

with water on the outer surfaces of the bilayer. Triacylglycerols and diacylglycerols are more hydrophobic molecules that tend to form spherical oil droplets in water. This minimizes their interactions with surrounding water molecules and maximizes interactions between their hydrophobic hydrocarbon chains.

3.4 •

See also Figures 3-16 and 3-17 for representative amino acid structures and the properties of their side chains (*R* groups). The amino and carboxyl groups participate in peptide bond formation between amino acid subunits. If they are exposed (not part of a peptide bond), the amino group can assume a positive charge and the carboxyl group can have a negative charge, depending on the pH of the medium. The *R* group can consist of any of a number of different functional groups that confer different shapes and properties to the amino acid. Nonpolar *R* groups are found on hydrophobic amino acids; polar *R* groups are found on more hydrophilic amino acids. Acidic and basic amino acids have negatively and positively charged side chains, respectively. • The primary structure of a polypeptide influences its secondary and tertiary structures through the differing structural and chemical properties of the amino acids in the polypeptide chain. Interactions between amino acids within the chain, such as hydrogen bonding, ionic bonding, hydrophobic interactions, and disulfide bonding can result in the formation of complex folds and structural domains within the polypeptide.

3.5 •

See also Figs. 3-24a and 3-25. Pyrimidine subunits in RNA consist of cytosine and uracil. The 5-carbon sugar in RNA is ribose. To convert this sugar to deoxyribose found in DNA, the 3' hydroxyl group of the ribose would be removed, and if the pyrimidine base were uracil, a methyl group would

have to be added to convert it to thymine. 3.6 • Refer to the following pairs of figures to compare differences between the indicated molecules: pentose and hexose sugars—Figs. 3-6b and c; disaccharides and sterols—Figs. 3-8 and 3-15; amino acids and monosaccharides—Figs. 3-17 and 3-6; phospholipid and triacylglycerol—Figs. 3-13a and 3-12b; protein and polysaccharide—Figs. 3-18, 3-19, and 3-21, as well as 3-9b and 3-10b; nucleic acid and protein—Figs. 3-18, 3-19, and 3-21 and 3-25.

Figure Questions

FIG. 3-13 Unlike bilayer-forming phospholipids, triacylglycerols lack the hydrophilic head groups needed to associate with water. They would not be able to form organized bilayer structures. **FIG. 3-20** Secondary structure is based on a regular repeating sequence of atoms in the backbone. Insertion of an additional carbon atom between the α carbon and the peptide bond carbon in some amino acids would disrupt secondary structure by altering the distances between the atoms involved in hydrogen bond formation. **FIG. 3-21** Leucine and valine would associate through hydrophobic interactions. Alanine (a nonpolar amino acid) would not interact with serine (a polar amino acid). Lysine and arginine are positively charged, basic amino acids and would repel each other. Glutamic acid has a negative charge and would form an ionic interaction with positively charged lysine.

Test Your Understanding

1. d 2. b 3. e 4. c 5. c 6. a 7. a 8. b 9. c 10. e 11. b 12. b and c or c and d 13. Sulfur would not be able to form hydrogen or ionic bonds with positively charged atoms found in proteins and other biological molecules. 14. Hydrogen bonds and van der Waals interactions can produce strong bonding when many of these bonds and interactions occur within a region of a biological molecule. Examples include α -helical regions and β -sheet regions of proteins and van der Waals interactions between fatty acid chains of membrane lipids. 15. All forms of life share many common components of biological molecules, including the nucleotides of nucleic acids, amino acids of proteins, fatty acids of membrane and storage lipids, and monosaccharides found in complex carbohydrates. These suggest that the use of these building blocks to form many different types of biological structures evolved early in the history of life. 16. Although there are very large combinations of amino acid sequences that can be generated for polypeptides, evolutionary processes select only the small number of sequences that have structures and functions that provide a selective advantage to the organism. 17. The existence of only one of two different kinds of enantiomers for amino acids suggests that the first cells to evolve had L-amino acids and that this feature has been conserved in all their descendants.

Chapter 4

Checkpoint

4.1 • Because cells, the basic units of life, only come from pre-existing cells, it follows that their lineage extends to very ancient times. • Membrane barriers are required to maintain the appropriate internal chemical environments for cellular functions. • DNA is used for information storage in all cells. • ATP is one convenient form of chemical energy used by all cells. • Small surface areas relative to large internal volumes prevent/restrict the movement of materials into, out of, and throughout the cells. **4.2** • Magnification that exceeds the limits of resolution (the equivalent of sharp focus) cannot improve the observation of fine structural details. • Each method provides different information about the structure or function of a cellular component. For example, microscopy can reveal the location of a protein within the cell and its association with cellular structures. Immunoprecipitation provides information about the quantity of the protein and other proteins that bind to it. Biochemical analyses provide structural and functional information about the protein. **4.3** • DNA, cell membranes, protein synthesis. • Plants have cell walls, chloroplasts, vacuoles, and plasmodesmata. • Membrane-enclosed organelles provide cellular compartments with unique chemical environments for specialized functions. Membranes serve as work surfaces for enzyme systems. Energy can be stored across membranes as electrochemical gradients. **4.4** • Almost all of the DNA in the cells is stored inside the nucleus. Information stored in the DNA must be transcribed into mRNA molecules, which must be transported through pores in the nuclear membrane to the cytoplasm, where proteins are manufactured by ribosomes. • The nuclear envelope and nuclear pores provide selective entry and exit for large macromolecules and macromolecular complexes, such as RNAs, ribosomes, nuclear proteins, etc. For example, proteins from the cytoplasm can only be transported through a pore if they have an NLS as part of their protein sequence • Large molecules, such as large proteins, RNA molecules, and macromolecular complexes are bound to specialized proteins that selectively import their “cargo” into or out of the nucleus through the nuclear pores. Small molecules such as ions and small polypeptides can freely diffuse through the nuclear pores. **4.5** • The rough ER typically consists of flattened membranous sheets that are studded with ribosomes on the cytosolic membrane surfaces. A primary function of the rough ER involves the synthesis of membrane proteins and proteins that are translocated through the ER membrane into the ER lumen. The smooth ER is typically made up of tubular membranous structures. Some regions of the smooth ER carry out membrane and storage lipid biosynthesis; others are involved in numerous functions including detoxification reactions, calcium storage, and various protein modifications. • The *cis* face of the Golgi complex receives proteins from membrane vesicles derived from the

ER and initiates modification of those proteins. The proteins are sequentially modified as they move through the Golgi complex. At the *trans* face of the Golgi complex, proteins are sorted into specialized transport vesicles that are targeted to the plasma membrane or other organelles in the cell such as lysosomes. • See Figure 4-15 for steps in the manufacture and secretion of cellular proteins. • Chloroplasts and mitochondria are organelles that contain multiple membrane compartments involved in the conversion of energy from one form to another. A major function of mitochondria is the breakdown (oxidation) of carbon compounds to form ATP. A primary function of chloroplasts is the capture of energy from light that is then stored in reduced carbon compounds. (See Fig. 4-19.) **4.6** • Cytoskeletal structures maintain cell shape, anchor intracellular structures and membranes, and are involved in the movement of cells and intracellular organelles. The endomembrane system is involved in many different cellular functions, including protein biosynthesis and modification, membrane formation, and membrane trafficking. • Microtubules and microfilaments are fiber-like structures that can be rapidly assembled and disassembled. Both are involved in different types of cellular and intracellular movements. Microtubules are hollow cylinders that can serve as intracellular tracks for organellar movement using molecular motors. Microtubules are also components of cilia and flagella used for cellular locomotion. Microfilaments can generate force and intracellular movement by rapidly assembling and disassembling. Combined with motor proteins such as myosins, microfilaments can also generate force and intracellular movement. • Microtubules are bundled, cylinder-like elements of cilia and flagella; they provide movement when bent by microtubule associated motor proteins such as dynein. **4.7** • The glycocalyx surrounds most cells as a cell coat that extends from the plasma membrane. It is formed by polysaccharides. • Fibronectins are extracellular matrix (ECM) glycoproteins that bind to integrins, which are plasma membrane receptor proteins.

Figure Questions

FIG. 4-11 Ribosomes are assembled in the nucleus and move from the inside of the nucleus to the cytosol through the nuclear pores. **FIG. 4-12** The protein fragment containing the hypothetical NLS sequence would bind to the importin attached to the beads. **FIG. 4-15** The vesicles would be unable to dock with the plasma membrane and release their contents. **FIG. 4-19** Cells would break down the available glucose, but would not be able to produce glucose in the chloroplasts. **FIG. 4-22** In either case, the cell would not be able to maintain its appropriate shape or move. **FIG. 4-26** Cilia would not be able to bend if the linking proteins were inflexible or absent.

Test Your Understanding

9.

See also Figs. 4-20 and 4-21. 10. None of the measurements agree. Observer 2 is most likely correct if the cells are prokaryotic ($0.002 \text{ mm} = 2 \mu\text{m}$); observer 3 is most likely correct if the cells are eukaryotic ($2 \times 10^4 \text{ nm} = 20 \mu\text{m}$). 11. Consider the following in formulating your answer: Membranous organelles provide the cell with compartments with unique environments. Fibrous cytoskeletal components provide for structure and movement. 12. Mutant a is probably defective in the formation of ER-derived transport vesicles or in movement of vesicles to the Golgi; mutant b probably has a defect in the formation of secretory vesicles on the *trans* face of the Golgi complex. 13. In formulating your answer, consider features common to all cells, including plasma membranes, ribosomes, DNA, and ATP. 14. Consider the origins and applications of different methods used to study the structures and functions of cells.

Chapter 5

Checkpoint

5.1 • Phospholipids and sterols are the primary determinants of membrane lipid bilayer fluidity.

- See also Figs. 5-4 and 5-6.

- See Fig. 5-8. Sugars are added to proteins in the lumens of the ER and Golgi complexes. **5.2** • Materials move across bilayers through transmembrane proteins that form highly selective channels or pumps for different types of molecules. • Some membrane proteins respond to extracellular signal molecules. Extracellular parts of some transmembrane proteins can bind or link to proteins on the surface of neighboring cells. **5.3** • Gases, water, as well as very small, nonpolar molecules. • Channels function as highly selective pores for specific ions or molecules. Transporters bind specific ions or molecules and change shape to move bound substrates across membranes. • Aquaporins are specific channel proteins that move water rapidly across the bilayer. **5.4** • Isotonic conditions result in no change in plant or animal cells. Under hypertonic conditions plant cells undergo plasmolysis due to water loss; they become turgid under hypotonic conditions. Hypertonic conditions cause animal cells to shrink; under hypotonic conditions they swell and may possibly burst. • The energy source for diffusion and facilitated diffusion is a chemical concentration gradient. • The net movement of particles in a concentration gradient is from a region of high concentration to low concentration. Simple diffusion and facilitated diffusion do not differ in the direction of net particle movement. **5.5** • Active transport requires a source of metabolic energy, such as ATP. • In cotransport, the transport of a substance down its concentration gradient provides the energy to drive the transport of the other substance against its concentration gradient. **5.6** • Both exocytosis and endocytosis move materials across the plasma membrane by vesicular transport mechanisms. • Phagocytosis moves large solid particles across the membrane; pinocytosis moves dissolved molecules. • The steps for the sequence of events for receptor-mediated endocytosis are outlined in Figure 5-22. **5.7** • Both desmosomes and tight junctions form strong attachments between neighboring cells. Desmosomes form strong sheets of cells; tight junctions prevent passage of materials through intercellular spaces. • Both plasmodesmata and gap junctions allow the movement of water, ions, and small molecules between the cytosols of neighboring cells. Gap junctions form protein-based channels between neighboring cells; plasmodesmata form continuous membrane-lined channels between the plasma membranes of neighboring cells.

Figure Questions

FIG. 5-5 The blue fluorescence would be distributed over the entire hybrid cell, while the proteins labeled with the green fluorescent antibody that are linked to cytoplasmic microtubules, would tend to remain on the “mouse side” of the hybrid cell.

FIG. 5-16 If equal numbers of Na^+ and K^+ ions were moved in each pump cycle, chemical gradients of the two different ions would be generated, but there would be no electrical gradient produced. **FIG. 5-18** The energy source for glucose transport is the cotransport of Na^+ ions down their concentration gradient. If the Na^+/K^+ pump were inhibited, the Na^+ gradient would

Answers / **A-17**

disappear, blocking the ability of the symporter to transport glucose. **FIG. 5-22** An LDL-receptor protein with a missing membrane-spanning region would be a soluble protein. Cells can only internalize LDL particles that are bound to receptors that are anchored to the plasma membrane. Humans who have receptors with no membrane spanning region exhibit very high levels of cholesterol in the blood because their cells are unable to capture the LDL particles and remove them from the bloodstream.

Test Your Understanding

1. c 2. e 3. a 4. b 5. d 6. e 7. b 8. e 9. e 10. The stimulated cells have ten times as many GLUT 4 proteins in their plasma membranes as unstimulated cells. 11. Consider that plant cells are held in relatively fixed positions by their cell walls, and also that plant cell walls may act as barriers to many types of molecules. 12. Consider that the properties of cell membranes include their ability to form compartments that maintain unique chemical environments. Can you think of other ways this could have been accomplished in the origin of life? 13. Early evolution of transport proteins would have greatly improved the ability of cells to maintain high internal concentrations of essential molecules and allowed cells to interact with their external molecular environments in a controlled way. These functions would have needed to be provided by some other mechanism if transport proteins had evolved later.

Chapter 6

Checkpoint

6.1 • The sequence of events involved in cell signaling are: *signal transmission* (synthesis and release of signal molecules), *signal reception* (binding of signals to target cell receptors), *signal transduction* (conversion and amplification of extracellular signals to intracellular signals), and *response* (conversion of the final signal into a cellular response that alters some cellular process). • Signal transduction results in the conversion of an extracellular signal into an intracellular form. Multiple intracellular signals are typically produced in the process, activating and/or deactivating multiple genes and proteins. **6.2** • Neurotransmitters are molecules that transmit signals across synapses between adjacent nerve cells. • Animal hormones are typically secreted by cells into the interstitial fluid. Some may bind to neighboring target cells, whereas others enter the blood to be transported to distant targets. • Endocrine and paracrine regulation are similar in that both involve the production of hormones secreted by ductless glands into the interstitial fluid. Paracrine hormones act locally, diffusing directly to their target cells. Endocrine regulation typically involves the transport of hormones through the blood to other parts of the body. **6.3** • Receptor proteins have binding sites that recognize

specific signal molecules. • Receptor up-regulation occurs in response to low concentrations of signaling molecules, increasing the sensitivity of that cell to that particular signal. Receptor down-regulation occurs when concentrations of signaling molecules remain high over extended times, decreasing the sensitivity of the down-regulated cell to that specific signal. • Cell-surface receptors contain an external *signal-binding domain*, a *membrane-spanning domain*, and an *internal cytoplasmic domain*. Each type of cell-surface receptor contains a unique signal-binding domain that binds a specific type of signal molecule. • Intracellular receptors bind signal molecules that can diffuse into the cell through the plasma membrane. The activated intracellular receptors are typically transcription factors that regulate the expression of specific genes. **6.4** • The binding of a signal molecule to a cell surface receptor alters the shape of the receptor protein, resulting in conformational changes in its intracellular domain. These changes trigger the activation of intracellular enzymes that produce or activate intracellular signaling molecules. For example, a signaling molecule binds to a receptor that activates a G protein; adenylyl cyclase is activated and catalyzes the conversion of many ATPs to cyclic AMP; cyclic AMP activates many protein kinases, which phosphorylate many proteins, leading to one or more responses. • Second messenger molecules are produced intracellularly in large quantities in response to an extracellular signal. • Scaffold proteins tightly organize the proteins involved in a signal transduction pathway so that they can interact efficiently. Loss of a scaffold protein could result in significant slowing of the signaling pathway, reducing the effectiveness of the response. **6.5** • Cells respond to signals by opening or closing ion channels, altering enzyme activities, or by changing patterns of gene expression.

Refer also to Figures 6-12 and 6-14 as examples of signal amplification through signal transduction pathways. • The failure to terminate signal transmission can lead to maintenance of the signal, resulting in continuation of a now-inappropriate response such as a failure to close certain ion channels. 6.6 • The observation that choanoflagellates and animals have similar protein kinases suggests that cell signaling became important at very early stages of animal evolution.

Figure Questions

FIG. 6-2 If a cell were exposed to a drug that blocked the activity of signaling molecule A, signal molecule B and other signaling molecules downstream of B would not be activated. There would be no changes in membrane permeability, metabolic processes, and gene expression controlled by that signaling pathway. **FIG. 6-12** If the Ras protein is continuously activated, any of the downstream components of the signaling pathway (Raf, Mek, or ERK) might prove to be good candidates for a drug target aimed to prevent cancerous growth. All of these components act as steps in the pathway to activation of cellular growth. **FIG. 6-13** If the altered LH receptor were activated in the absence of LH, its signaling pathway would be continuously activated, resulting in the constant activation of oocyte maturation and ovulation.

Test Your Understanding

1. a 2. e 3. d 4. c 5. a 6. a 7. c 8. d 9. c 10. Binding of a hormone to a G protein-linked receptor results in the formation of many second messengers along with the activation of a number of different protein kinases. Each of these types of signals can result in the activation (or deactivation) of different sets of genes and enzymes, leading to the blocking of DNA synthesis, directional growth toward a mating partner, and other physiological events associated with mating in yeast. 11. The identification of hundreds of protein kinase genes in humans indicates that these enzymes play major roles in the regulation of many different physiological functions in human cells. Since each kinase activates or deactivates a specific set of proteins in response to specific cellular signals, the large number of different kinases indicates that many different types of responses are controlled by these enzymes. 12. d 13. b 14. You might hypothesize that plants and animals have common ancestors. Because they share many of the basic molecular components involved in membrane and organellar structure, growth, metabolism, and cell division, a number of these molecules might have been selected as molecular signals. Similarities in plant and animal signaling include protein kinases and G protein receptors that employ GTP or trigger the synthesis of modified forms of ATP (cAMP) as signals. For the differences in signaling, consider the different structures and functions of plant and animal cells. Plants have cell walls and cells communicate through plasmodesmata, whereas animals can communicate via the extracellular fluid through receptors on membrane surfaces. Plants also respond to different types of stimuli, including

light, which could lead to the evolution of receptors and different types of light-sensitive signal molecules. 15. The occurrence of G protein-linked receptors and signal transduction pathways found in plants and animals as well as fungi and algae suggests that these signal pathways may have evolved very early in a common ancestor of all these organisms. This suggests that these molecules and pathways existed in ancient organisms early in the evolutionary process. 16. Tyrosine kinase signaling proteins trigger different types of signal transduction pathways in different cell types, depending on which types of signal transduction proteins are present. Drugs that inhibit tyrosine kinases in cancer cells may also inhibit tyrosine kinases that may be required for certain essential cellular functions in normal cells.

Chapter 7

Checkpoint

7.1 •

Kinetic energy is used to stretch the spring. Work is performed. The stretched spring has stored potential energy. Potential energy is converted to kinetic energy as the spring is released. See also Fig. 7-1. 7.2 • First law of thermodynamics: Energy cannot be created or destroyed, but can be converted from one form of energy to another. Second law of thermodynamics: When energy is converted from one form to another, some of the usable energy is converted to heat and dissipated into the surroundings. This results in the amount of usable energy in the universe available to do work decreasing with time. • Organisms succeed in the struggle with the second law because they are open systems. They can capture energy from their surroundings to do work. Although this allows living systems to increase in order, the total entropy of the universe (organisms plus their surroundings) always increases over time. 7.3 • In a reaction in which enthalpy decreases and entropy increases, ΔG has a negative value. The reaction is exergonic. • Reaction 2 can do work. 7.4 • (1) $X + \text{ATP} \rightarrow X - \text{P} + \text{ADP}$; (2) $X - \text{P} \rightarrow Y + \text{P}_i$. If the ratio of ATP to ADP were to become 1:1, ATP-requiring reactions would not work effectively because the ATP/ADP system would be near equilibrium. 7.5 • Reduced compounds have

more energy available than oxidized forms. They contain electrons that can be transferred to oxidizing agents, transferring energy in the process. **7.6** • An enzyme reduces the energy of activation of a chemical reaction, speeding up the reaction. • An active site of an enzyme is a region involved in the conversion of a substrate to its product. An allosteric site is a binding site on the enzyme for a molecule that regulates the enzyme's activity. • Temperature and pH affect an enzyme's structure, and thus its activity, by promoting the formation or breaking of hydrogen bonds and the number of electrical charges within the protein. • Allosteric inhibition is noncompetitive. The allosteric regulatory molecule binds at a site other than the active site of the enzyme.

Figure Question

FIG. 7-10 The reaction would not proceed if ΔG had a positive value. A reaction cannot proceed spontaneously if the products will have more energy than the reactants.

Test Your Understanding

1. e 2. d 3. b 4. c 5. b 6. c 7. b 8. b 9. b 10. e 11. a 12. The use of ATP/ADP by all organisms suggests that their role in energy metabolism evolved very early in the history of life among ancestors that are common for all living organisms. 13. The statement misinterprets the second law of thermodynamics. Entropy always increases only in a closed system such as the entire universe. Organisms are open systems that can extract energy from their surroundings, which can be used to build greater complexity. 14. The reaction is exergonic. The free energy of the products is less than the free energy of the reactants. 15. Reaction 2 is capable of performing work. 16. If the inhibition is competitive, increasing the succinate concentration should reverse the inhibition of the enzyme.

Chapter 8

Checkpoint

8.1 • Glucose loses electrons, becoming oxidized. • Oxygen serves as an electron acceptor in most cells. **8.2** • ATPs available from one molecule of glucose: (1) glycolysis produces a net yield of 2 ATPs from substrate-level phosphorylation in the cytosol; (2) acetyl CoA formation in the mitochondria does not produce ATP; (3) the citric acid cycle produces a net yield of 2 ATPs from substrate-level phosphorylation in the mitochondria; (4) oxidative phosphorylation produces a net yield of 32–34 ATPs produced from NADH and FADH_2 in the mitochondria through electron transport and chemiosmosis. • The electron transport chain functions in the transport of H^+ ions from the mitochondrial matrix across the inner mitochondrial

membrane, establishing a proton gradient. Energy stored across the mitochondrial inner membrane in the form of the proton gradient powers ATP synthesis as protons flow back across the inner membrane through the ATP synthase complex. The ATP synthase complex catalyzes the formation of ATP using the energy from proton movement through the complex. • NAD^+ and FAD accept electrons derived from the breakdown of glucose and its products, forming NADH and FADH_2 . These high-energy electrons are then passed to membrane proteins in the electron transport chain, powering the transport of H^+ ions across the inner membrane to establish the proton gradient used to synthesize ATP. Oxygen is the terminal electron acceptor from the electron transport chain. In the process it is reduced to H_2O . • If most of the ADP in the cell were converted to ATP, oxidative phosphorylation would slow because of a lack of ADP to be converted to ATP. **8.3** • Humans obtain energy from a low-carbohydrate diet by converting lipids and other biological molecules in their food into molecular intermediates of glycolysis or the citric acid cycle. • Amino acids from food supplies must be deaminated before the carbon chain can be metabolized through glycolysis or the citric acid cycle.

Refer also to Figure 8-13. Show in your diagram that fatty acids are broken down to form acetyl coenzyme A before being metabolized through aerobic respiration in the citric acid cycle. **8.4** • An equivalent number of hydrogen atoms removed from glucose during glycolysis are transferred to NAD^+ to form NADH. When oxygen is present, the NADH is recycled to NAD^+ through electron transport and oxidative phosphorylation. An equivalent number of these hydrogen atoms is used in the formation of H_2O when the electrons are passed to molecular oxygen during that process. In the absence of oxygen, NAD^+ is recycled from NADH by passing the electrons (and an equivalent number of hydrogen atoms) to organic molecules, forming ethanol and carbon dioxide or lactate. • The ATP yield from fermentation is much lower than that from aerobic respiration because the energy released from the glucose in the form of reduced NADH and FADH_2 cannot be used to form large amounts of ATP through electron transport and oxidative phosphorylation. • Chemiosmosis is not involved in fermentation, but anaerobic respiration does involve an electron transport chain (with a terminal electron acceptor other than oxygen) and chemiosmosis.

Figure Questions

FIG. 8-3 In glycolysis, 2 molecules of G3P will yield 4 ATPs, whereas glucose will consume 2 molecules of ATP in the formation of G3P, yielding a net gain of only 2 ATPs. Two molecules of G3P will yield 4 molecules of ATP and 2 molecules of NADH in glycolysis; no energy is captured from pyruvate in glycolysis because it is the end product in the pathway. **FIG. 8-8** If complex III were missing, complex I and complex II would not be able to pass on their electrons down the chain to complex IV and molecular oxygen. Complex I and complex II would remain in a reduced state and would not be able to recycle NADH and FADH₂ to the NAD⁺ and FAD needed to accept new electrons generated from the citric acid cycle. **FIG. 8-9** If the cells were placed in a basic (low H⁺ concentration) environment, a proton gradient would not exist and ATP synthesis would not take place. **FIG. 8-11** If ATP synthases were removed, electron transport would still create a proton gradient across the membrane, but ATP synthesis would not take place. **FIG. 8-14** Anaerobic respiration, because in that process high-energy electrons are transferred from NADH to an electron transport chain that synthesizes ATP by chemiosmosis.

Test Your Understanding

1. d 2. a 3. a 4. b 5. c 6. d 7. d 8. e 9. b 10. c 11. d 12. The proton gradient represents a state of low entropy because the proton gradient is highly organized with high H⁺ concentrations in the intermembrane space and low H⁺ in the matrix. 13. The first phase of glycolysis involves the coupling of the exergonic reactions of ATP hydrolysis to the endergonic phosphorylation of glucose to form fructose 1,6 biphosphate. The second phase of glycolysis involves the coupling of the exergonic reactions of the hydrolysis of phosphate and the removal of electrons from G3P to the endergonic phosphorylation of ADP to form ATP and the reduction of NAD⁺ to form NADH. 14. If the inner mitochondrial membrane were readily permeable to H⁺ ions, the coupling of electron transport to ATP synthesis could not occur because a proton gradient could not be formed across the membrane.

15.

Refer also to Figure 8-11 in constructing your diagram. 16. When you lose weight, carbon-containing compounds (especially fatty acids) become oxidized, yielding carbon dioxide and water. 17. The universal occurrence of the identical reactions

of glycolysis in all organisms indicates that glycolysis evolved at early stages in the origin of life, in cells that became the ancestors of all modern organisms. 18. The need for photosynthetic organisms to continuously replenish oxygen in the atmosphere today indicates that aerobic respiration could not have evolved without the previous evolution of oxygen-releasing photosynthetic processes.

Chapter 9

Checkpoint

9.1 • Red light has the longer wavelength. • Violet light has the higher energy per photon.

9.2 •

Refer also to Figure 9-4b. The line should be colored green. One side of the line should be labeled the thylakoid lumen. The other side should be labeled the chloroplast stroma. • The matching of the action spectrum of photosynthesis with combined spectra of chlorophylls *a* and *b* indicates that these molecules are the primary mechanism for capturing light energy for photosynthesis. Photosynthesis would be less efficient if their absorption spectra coincided exactly because fewer wavelengths of light in the red and blue regions would be captured, losing those sources of energy. • Fluorescence results from release of a low-energy photon from a molecule that has captured a photon with higher energy. That low-energy photon cannot be used to drive photosynthesis. **9.3** • Molecular oxygen is more oxidized than the oxygen in a water molecule. • Carbon fixation reactions are dependent on ATP and NADPH molecules produced during the light-dependent reactions of photosynthesis. **9.4** • Molecular oxygen is released as a waste product through the splitting of water as electrons are transferred to photosystem II. In aerobic respiration, molecular oxygen is the terminal electron acceptor for the mitochondrial electron transport chain, forming water in the process. • Photophosphorylation of ADP to form ATP involves the transport of electrons energized in photosystem II. Their energy is used to form a proton gradient across the thylakoid membrane. ATP is formed when protons diffuse back, through the ATP synthase complexes in the thylakoid membrane. • Cyclic electron transport through photosystem I cannot drive photosynthesis. While ATP can be generated through this process, it does not produce NADPH required for photosynthesis. **9.5** • Phase 1 of the Calvin cycle (CO₂ uptake phase) involves the fixation of carbon when CO₂ reacts with RuBP to form PGA. In phase 2 (carbon reduction phase), PGA is converted to G3P using energy from ATP and NADPH formed during the light-dependant reactions. G3Ps are converted to

carbohydrate or remain in the cycle in phase 3 (RuBP regeneration phase, which also requires ATP energy). • A decrease in entropy occurs during CO₂ uptake due to the fixation of the CO₂ into a carbon skeleton by combining it with RuBP. This reaction is exergonic because RuBP is a high-energy molecule. Its formation required energy from ATP and NADPH earlier in the cycle. • Photorespiration requires oxygen and produces CO₂ and H₂O; it differs from aerobic cellular respiration in that ATP is not produced. • C₃, C₄, and CAM plants all have rubisco, which is used to fix CO₂ through the reaction with RuBP at the beginning of the Calvin cycle. Only C₄ and CAM plants employ PEP carboxylase as a way of initially capturing CO₂ prior to the Calvin cycle. 9.6 • Green plants obtain energy from light. They obtain carbon through the fixation of CO₂. Humans obtain energy and carbon from reduced carbon compounds derived from food. 9.7 • Root cells obtain energy and organic molecules from sugars transported through plant vascular tissues from photosynthetic tissues. • Molecular oxygen in the atmosphere is produced by photosynthetic organisms.

Figure Questions

FIG. 9-7 We would expect the bacteria to be distributed in the area corresponding to the yellow/green part of the spectrum if their photosynthetic pigments had a maximal absorption at those wavelengths. **FIG. 9-11** If photosystem I were missing, there would be no terminal electron acceptor to receive the electrons derived from water in photosystem II, so all photosynthesis would stop. **FIG. 9-13** If an inhibitor prevented protons from being pumped across the thylakoid membrane, ATP could not be synthesized using energy captured by photosystem I. As long as NADP⁺ is available, NADPH could be produced by electron transport through photosystems II and I. **FIG. 9-14** If the 2:10 ratio of G3P molecules leaving the Calvin cycle were to become a 4:8 ratio, the cycle would run down because the pool of G3P would become depleted with each turn of the cycle, leaving insufficient G3P molecules to continue the formation of RuBP.

Test Your Understanding

1. a 2. d 3. a 4. e 5. c 6. a 7. c 8. b

9.

A-22 / Appendix E

Refer also to Figure 9-13. The interior compartment should be labeled thylakoid lumen. The exterior should be chloroplast stroma. The proton gradient should show high levels in the lumen and low in the stroma. ATP is synthesized in the stroma.

10.

Compare your sketch to Figure 8-11. For chloroplasts, protons are pumped into the innermost compartment (the thylakoid lumen); in mitochondria protons are pumped out of the innermost compartment (the matrix). The direction doesn't matter as long as the ATP synthase complex is oriented correctly with respect to the proton gradient. 11. Not all autotrophs use energy from light. Chemoautotrophs capture energy from reduced inorganic compounds such as hydrogen sulfide, nitrite, or ammonia. 12. All actively metabolizing plant cells require energy (in the form of ATP, NADH, and other reduced compounds) for growth, development, and maintenance that is generated through mitochondrial functions. 13. High-energy electrons in glucose became energized during the light-dependant reactions of photosynthesis. 14. Photoautotrophs could sustain life on Earth without the presence of chemoheterotrophs. Chemoheterotrophs, however, could not survive without sources of energy and carbon skeletons provided by photoautotrophs. 15. The common occurrence of ATP synthase complexes among bacteria, chloroplasts, and mitochondria suggests that these enzyme systems must have evolved early in the history of life. 16. The absorption spectrum indicates that these pigments absorb purple and blue light. Their color would be a mixture of reflected green, yellow, orange, and red light that is not absorbed by the pigments. 17. Some strategies for increasing the food supply might involve engineering food crops to more efficiently carry out photosynthesis and carbon fixation. One strategy might be to produce a more efficient form of the carbon-fixing enzyme rubisco. Another might be to increase the productivity of traditional C₃ food crops for growth in arid and hot climates by incorporating C₄ and CAM enzyme systems into the plant photosynthetic tissues.

Chapter 10

Checkpoint

10.1 • Informational units on chromosomes are called genes. Genes consist of sequences within DNA molecules that encode information needed to carry out one or more specific cell functions. • DNA found within a nucleus is very long compared to the diameter of the nucleus. In order to address the large differences between chromosome length and nuclear dimensions, DNA molecules are packaged in a highly organized way in chromosomes. **10.2** • The stages of the cell cycle consist of G_1 , S, G_2 , and M phases. DNA is replicated during the S phase. • The stages in mitosis are: *prophase*—chromosomes shorten and condense; *prometaphase*—chromosomes begin to move to the cell's midplane; *metaphase*—duplicated chromosomes align on the metaphase plate; *anaphase*—chromatids (each now a chromosome) separate and move toward opposite poles of the cell; and *telophase*—two nuclei are formed and cytokinesis usually occurs, giving rise to two cells. **10.3** • Cell-cycle checkpoints temporarily block key events in the cell cycle from being activated, ensuring that the previous phase of the cell cycle has been completed before the cell cycle can proceed. • Two types of molecular controls that control the onset of different stages of the cell cycle are (1) the association of Cdk with cyclin to form M-Cdk, which triggers the M phase, and (2) the degradation of M-Cdk, allowing daughter cells formed by mitosis to enter G_1 . **10.4** • Homologous chromosome pairs are present in diploid cells. Only one member of a homologous chromosome pair is present in a haploid cell. • Meiosis is a process of cell division resulting in the formation of haploid cells. Mitosis is a process of cell division that produces daughter cells that are genetically identical to the original cell. • Haploid cells can divide by mitosis. They cannot undergo meiotic cell division because they do not contain pairs of homologous chromosomes. **10.5** • In animals, somatic cells are produced by mitosis, and gametes by meiosis. In plants, cells of the $2n$ sporophyte and n gametophyte generations are produced by mitosis. Plant spores (n) are produced by sporophyte cells by meiosis; plant gametes are produced by gametophyte cells by mitosis. • Many protists remain haploid throughout most of their life cycle. Two haploid gametes can fuse through fertilization, however, to form a diploid zygote, which subsequently undergoes meiosis to restore the haploid chromosome number.

Figure Questions

FIG. 10-4 Histone H1 is involved in the packing of 10-nm nucleosomes, forming 30-nm packed nucleosome fibers. **FIG. 10-8** If cohesins failed to separate, two daughter chromosomes might move to the same pole, resulting in one cell that has two copies of a given chromosome and a sister cell that has no copies of that same chromosome. If the chromatids

dissociated prematurely in late prophase, the separated chromosomes would not arrange properly on the metaphase plate and might not separate equally into the two daughter cells. **FIG. 10-10** If spindle microtubules disassembled at their polar ends, the distances between the bleached areas and the poles would be decreased.

FIG. 10-13

Refer also to Figure 10-9. If the cell were arrested at the metaphase–anaphase checkpoint, chromosomes would stay aligned at the metaphase plate of the cell. **FIG. 10-14** If cyclin were not degraded in step 4, cells formed by mitosis would not enter into the G_1 phase.

Test Your Understanding

1. c 2. d 3. e 4. d 5. c 6. c 7. b 8. b

9.

Refer also to Figures 10-6 and 10-7. 10. The DNA content of a cell doubles as the cells progress through the S phase of interphase. The number of chromosomes does not change. At the end of the S phase, each chromosome consists of two identical DNA molecules as chromatids. 11. For a cell with 5 chromosomes:

	Number of Duplicated Chromosomes	Number of Unduplicated Chromosomes	Number of Kinetochores
Prophase (number per cell)	5	0	10
Metaphase (number per cell)	5	0	10
Telophase (number per nucleus)	0	5	5

The cell is haploid because an odd number of chromosomes indicates that there are no pairs of homologous chromosomes. 12. For a diploid cell with 14 chromosomes:

	Number of Duplicated Chromosomes	Number of Unduplicated Chromosomes	Number of Tetrads
Beginning of prophase I (number per cell)	14	0	0
End of prophase I (number per cell)	14	0	7
End of telophase II (number per nucleus)	0	7	0

13. Honeybee drones are produced by an asexual mechanism with no fusion of gametes. 14. Seeds develop from a flower pollinated by the same plant through sexual reproduction resulting from the fusion of two haploid gametes. 15. The chromosomal mechanisms of mitosis are similar in organisms as diverse as seaweeds and mammals, indicating an evolutionary relationship between these groups of organisms. 16. During unfavorable conditions, sexual reproduction involving meiotic recombination and fusion of gametes would ensure a more genetically diverse generation than the identical progeny produced by asexual reproduction. Greater genetic diversity within a generation increases the chance of survival of at least some offspring as new environmental conditions emerge.

Chapter 11

Checkpoint

11.1 • A single diploid individual can have a maximum of two different alleles for a genetic locus. • Segregation cannot be demonstrated between crosses of either two homozygous dominant individuals or two homozygous recessive individuals. All progeny in those crosses will either show a homozygous dominant or homozygous recessive phenotype. • A monohybrid cross involves only one locus and cannot be used to demonstrate independent assortment. To observe independent assortment, you need individuals heterozygous for two different loci. **11.2** • The F_1 individuals crossed would be $YyRr \times YyRr$. To produce yellow, round seeds, a plant must be $Y_R_$ (probability in this cross = $\frac{9}{16}$). • The product rule and the sum rule were used to obtain the result. **11.3** • If two loci are unlinked, the ratio of genotypes to phenotypes in a two-point test cross is 1:1:1:1. • Unlinked genes reside on different chromosomes. Crossing-over occurs only between homologous chromosomes. The mechanism of recombination for unlinked genes is independent assortment. • The map distance between the two loci is 5 map units. • The Y chromosome determines

male sex in humans and most other mammals. • Dosage compensation is required in mammals because females have roughly twice as many genes on their two X chromosomes as males, who have only one X chromosome. In females, one X chromosome is inactivated in most cells to balance the number of active X chromosome genes between males and females. One of the two X chromosomes is active in some cells, and the other X is active in other cells, leading to variegated expression (on a cell by cell basis) of many X-linked genes. **11.4** • For ABO blood types, the A allele and the B allele are codominant, and are both fully expressed in heterozygotes. For traits with incomplete dominance, both alleles are expressed, but the phenotype is a mixture of the two traits, as in the pink flower color of heterozygous four o'clocks. • A trait with multiple alleles means that more than two different alleles for a locus can occur in a population. Only two alleles, however, can occur within an individual. Polygenic inheritance refers to a phenotypic trait that is produced by the additive action of alleles of more than one locus in an individual. • Pleiotropy is the ability of a gene to have multiple effects on the phenotype. Epistasis refers to the interaction between alleles of two different loci. • The *norm of reaction* refers to the range of phenotypic possibilities that can develop from a single genotype under different environmental conditions. In the case of the hydrangeas, the range may include a variety of pink, purple, and blue hues, but may not extend to other colors such as yellow.

Figure Questions

FIG. 11-3 All F_2 generation short plants are homozygous recessive. You would be able to discover the genotype of an F_2 generation tall plant by crossing it with an F_2 short plant. If the tall plant is heterozygous, you will obtain a 1:1 ratio of tall and short progeny. If it is homozygous dominant, all progeny will be tall (but heterozygous). **FIG. 11-4** The haploid cells would be spores if meiosis were occurring in a plant and gametes if it were occurring in an animal. **FIG. 11-6** You would expect the same results if the genotypes in the P generation were reversed. **FIG. 11-7** If only one black individual were produced from the test cross, the genotype of the black parent could be either homozygous or heterozygous. If a single brown individual were produced, the genotype of the black parent would be heterozygous. **FIG. 11-8** The results would be the same. Segregation and independent assortment do not act differently depending on parental genotype. **FIG. 11-9** The diagram would be drawn the same (refer to the answer for Figure 11-8). **FIG. 11-11** You would expect a similar excess of parental class progeny and a deficiency of recombinant class progeny, but the classes would be reversed. The parental classes would be $BbVv$ and $bbVv$. The recombinant classes would be $BbVv$ and $bbvv$.

FIG. 11-12

FIG. 11-16 The calico cat would be female. If the cat were black or orange, it could be either a male, or a female homozygous for black or orange. **FIG. 11-17** A pink-flowered (heterozygous) plant crossed with a white-flowered (homozygous) plant would yield a 1:1 ratio of pink- and white-flowered plants. Crossing a pink plant with a red (homozygous) plant would yield a ratio of 1:1 red and pink progeny. **FIG. 11-18** Two *PpRr* chickens would produce offspring in the ratio of 9 walnut, 3 pea, 3 rose, and 1 single-combed. **FIG. 11-19** Two black labs could produce a yellow puppy if the parents were heterozygous (*BbEe*), producing a puppy with a *B_ee* or *bbee* genotype. **FIG. 11-20** Possible genotypes from the class in the middle include all combinations that include 3 “dark” alleles and 3 “light” alleles (*AaBbCc*, *AABbcc*, *AAbbCc*, *aaBBCC*, *aaBbCC*, *AaBBcc*, or *AabbCC*).

Test Your Understanding

1. d 2. c 3. c 4. e 5. c 6. b 7. The short-winged genotype is recessive. The parents were both heterozygous for wing length. 8. Hair length: *S* = short hair, *s* = long hair. Coat color: *B* = black, *b* = brown / tan. $BBss \times bbSS \rightarrow BbSs$ F_1 progeny (black, short hair). If two F_1 s are mated, probability of long hair is $\frac{1}{4}$, and the probability of brown/tan is $\frac{1}{4}$. $\frac{1}{4} \times \frac{1}{4} = \frac{1}{16}$. The probability of producing a long-haired, brown/tan cat is $\frac{1}{16}$. 9. Yes, Richard could be the child of the parents if both were heterozygous ($I^A i \times I^B i$). 10. Rooster: *PpRr*; Hen A: *PpRR*; Hen B: *Pppr*; Hen C: *PPRR*. 11. The cross is a two-point test cross; the loci are linked. Parental classes are *Aabb* and *aaBb*; recombinant classes are *AaBb* and *aabb*. The percentage of recombination between the two loci is 4.6%. The two loci are 4.6 map units apart. 12. Gene *A* is in the middle if *B* and *C* are 10 map units apart. Gene *C* is in the middle if *B* and *C* are 2 map units apart.

13. (a)

Refer also to Figure 11-4 to construct a diagram of gene segregation.

Refer also to Figure 11-9 to diagram alleles that undergo independent assortment.

Refer also to Figure 11-12 to construct a diagram of two linked loci that undergo recombination. 14. You cannot

usually discriminate between the phenotypes of heterozygous and homozygous individuals for genes that exhibit simple Mendelian dominant and recessive inheritance. You may be able to predict the phenotype of an individual if you know the genotype, but keep in mind that the phenotype may be influenced by the environment or by other genes (epistasis). 15. Linked genes recombine through crossing-over during meiosis. Unlinked genes are on nonhomologous chromosomes and recombine through independent assortment during meiosis. 16. The inherited variation among individuals that Darwin observed is caused by the different combinations of alleles of one or more loci found in each individual. 17. Sixty-four individuals were involved in the hypothetical cross. Of those, 1.6% ($\frac{1}{64}$) had the lightest skin possible and 1.6% had the darkest skin possible.

Chapter 12

Checkpoint

12.1 • Griffith's work showed that a genetic trait (virulence) could be transferred from one bacterial strain to another. This allowed Avery and his colleagues to determine that the trait was transferred by the DNA that was extracted from the donor strain. • Hershey and Chase knew that

proteins of bacteriophages could be specifically labeled with radioactive sulfur and that bacteriophage DNA could be specifically labeled with radioactive phosphorus, allowing them to determine which type of molecule entered a bacterial cell upon infection. **12.2** • Adenine, thymine, guanine, and cytosine nucleotides make up a single strand of DNA. They are linked together through their 5' phosphate groups that are covalently bonded to the 3' carbon of the deoxyribose subunit of the next base in the polynucleotide chain. • Watson and Crick determined that double-stranded DNA consisted of two single strands of DNA running in opposite directions to form a helix, with the nitrogenous bases stacked on the inside and their phosphodiester chains on the outside; the bases in the interior of the helix are hydrogen bonded to their complementary bases (A:T and G:C) on the opposite strand. • Chargaff's rules showed that in DNA molecules extracted from different organisms, the amount of adenine was equal to the amount of thymine and the amount of guanine was equal to the amount of cytosine. This corresponded to the base pairing rules for double-stranded DNA in Watson and Crick's model. **12.3** • Meselson and Stahl could separate and identify DNA strands from different generations of bacteria by labeling them with either ^{14}N or ^{15}N as they were being replicated. By showing that ^{15}N -labeled DNA progressed from a dense to intermediate and lighter densities in subsequent generations of growth on ^{14}N -labeled medium, they demonstrated that DNA was replicated by a semiconservative mechanism. • The two strands of a DNA molecule run in opposite directions. Because DNA polymerase can only add bases to a growing 3' end, one strand is replicated in a continuous manner, and the opposite strand is replicated discontinuously. • Eukaryotic cells require telomerase because their DNA is linear, resulting in shortened ends with each round of DNA replication. Bacterial DNA is circular and is replicated completely with each round of replication.

Figure Questions

FIG. 12-1 Heat-killed S cells treated by methods 1 or 2 would still transform the rough cells to virulence. Method 3 would prevent the S cells from transforming R cells into S cells. **FIG. 12-3** The Hershey–Chase experiments reinforced Avery, MacLeod, and McCarty's findings that genes are composed of nucleic acids by showing that only bacteriophage DNA is required to form new

bacteriophage particles composed of both DNA and protein. **FIG. 12-9** G:C base pairs are linked by three double bonds; A:T base pairs are linked by two double bonds. It would require more energy to separate the strands (to break the bonds) of G:C-rich DNA than A:T-rich DNA.

FIG. 12-11

Refer also to Figures 12-10b and c. Conservative replication would produce a light and heavy band after the first round of replication (no intermediate band). Dispersive replication would produce diffuse bands of intermediate density in the centrifuge after one and two replication cycles.

Test Your Understanding

1. c 2. d 3. d 4. e 5. b 6. d 7. b 8. e 9. d 10. b 11. a 12. b 13. Cancer cells are locked in a constant state of growth and cell division. They require active telomerase to maintain continuous cell division without losing essential chromosomal material.

Refer also to Figures 12-15 and 12-16 to construct your diagram. 15. In drafting your response, consider the properties the genetic material must have, including the ability to store information, the ability to be copied accurately from one generation to the next, and the ability to undergo stable mutations that persist in following generations. Then explain how these properties are found in the structure of DNA. 16. If the radioactive-labeled proteins were found inside the cells, Hershey and Chase would have to argue that the genetic information needed to replicate and assemble bacteriophages was encoded by proteins. 17. DNA is the universal molecule of inheritance in all cells. This supports evolutionary theory providing a common mechanism for inheritance and the ability to undergo stable changes in inherited traits, providing a source of variable traits for natural selection to act upon.

Chapter 13

Checkpoint

13.1 • The one-gene, one-enzyme hypothesis argued that each gene encodes the information to produce a single enzyme. • Garrod showed that a single recessive gene was associated with a missing enzyme; Beadle and Tatum showed that there was a one-to-one correspondence of genes with enzymes; Pauling demonstrated that a mutation in a single gene altered the structure of a single polypeptide chain, refining the definition of a gene (at that time) to “one gene, one polypeptide chain.” **13.2** • DNA (transcription) → RNA (translation) → polypeptide. • DNA and RNA are both polynucleotides consisting of strands of nucleotides linked together by phosphodiester bonds. They differ in that DNA molecules are typically double-stranded molecules with deoxyribose as the sugar. RNA molecules are typically single-stranded molecules with ribose as the sugar component. **13.3** • DNA and RNA polymerases are enzymes that assemble polynucleotide chains by adding nucleotides to a growing 3' end. They form phosphodiester linkages from nucleoside triphosphate subunits. DNA polymerases can only polymerize nucleotides from an existing 3' end of a DNA molecule that is hydrogen-bonded to a complementary strand; RNA polymerases do not require a 3' end of a

primer to copy a template DNA strand. • The transcribed RNA would read 5' AUG ACG UAU UAC UAA 3'. The nontemplate DNA strand would read 5' ATG ACG TAT TAC TAA 3'. • Eukaryotic mRNAs have a 3' → 5' 7-methylguanosine cap at the 5' end of the molecule and a poly-A tail at the 3' end of the message. **13.4** • Ribosomes are composed of two subunits. The small subunit contains a single RNA molecule and over 20 different proteins; the large subunit contains two RNA molecules and over 30 proteins. The ribosomal RNAs have catalytic functions and do not encode information about the amino acid sequence of proteins. • Initiation of protein synthesis involves binding of the small ribosomal subunit to the start codon region of the mRNA. The initiator tRNA binds to the start codon, followed by the assembly of the complete ribosome. Elongation is a cyclic process in which amino acids are added, one by one, linked by peptide bonds to the growing polypeptide chain. Elongation proceeds from the 5' end to the 3' end of the mRNA and from the amino end to the carboxyl terminal end of the polypeptide chain. Termination occurs when the ribosome encounters a stop codon in the mRNA. A release factor binds to the ribosomal A site, releasing the polypeptide chain and disassociating the ribosomal subunits and translation complex. • The anticodons are 3' UAC UGC AUA UUG AAA, and the corresponding amino acid sequence is NH₂–Met–Thr–Tyr–Asn–Phe–COOH. **13.5** • The main types of mutations are base-pair substitution mutations (either silent, missense, or nonsense mutations), frameshift mutations, or mutations involving mobile genetic elements. • Silent mutations do not alter the amino acid composition of the protein; missense mutations substitute one amino acid for another in the polypeptide; a nonsense mutation inserts a stop codon, resulting in a shortened polypeptide. Frameshift mutations alter the reading frame, usually resulting in the insertion of a stop codon a short distance from the mutation. **13.6** • RNA interference occurs when small RNA molecules interfere with the expression of genes or their transcripts. • A gene is a unit of inheritance. In molecular terms it is a DNA sequence that contains information used to produce an RNA or protein product. • Retroviruses use reverse transcriptase to synthesize a DNA strand that is complementary to the viral RNA. After the double-stranded DNA provirus is completed, it is integrated into the host cell's DNA.

Figure Questions

FIG. 13-2 Citrulline or arginine would support the growth of a strain missing both enzyme 1 and enzyme 2.

FIG. 13-4

template strand: 3' TAC TGA ACG CTT ACA AAG 5'
mRNA strand: 5' AUG ACU UGC GAA UGU UUC 3'

FIG. 13-9 RNA polymerase will require a helicase activity to unwind the DNA, exposing the template strand; a polymerase activity to form the phosphodiester bonds of the mRNA; and topoisomerase activities to reduce strain on the DNA as the double helix is uncoiled. Each of these activities may involve the actions of two or more proteins. **FIG. 13-12** A mutation in the polyadenylation signal of an mRNA would prevent it from being polyadenylated. This would probably prevent the mRNA from being exported from the nucleus. The absence of a poly-A tail would also affect the stability of the mRNA, as well as prevent it from being properly translated.

Test Your Understanding

1. e 2. a 3. b 4. d 5. b 6. a 7. e 8. c 9. a 10. d 11. b 12. e 13. Bacterial and eukaryotic mRNAs are both transcribed by RNA polymerase II enzymes. Transcription is started at initiation sequences that are downstream of the promoter site. Both types of mRNAs are transcribed in a 5' → 3' direction as the polymerase travels down the template strand in a 3' → 5' direction. Unlike bacterial mRNAs, the 5' ends of eukaryotic mRNAs are quickly capped after the initiation of transcription. Intron sequences in the eukaryotic pre-mRNA molecule are removed by spliceosomes and the remaining exons are spliced together. After the poly-A site (which is located 3' to the mRNA coding sequences) is transcribed, the pre-mRNA is cut and poly-A sequences are added to the 3' end of the transcript. Transcription of eukaryotic mRNA requires more energy because many of the nucleotides incorporated into the pre-mRNA are removed by intron splicing and are not required for protein synthesis. The formation of the poly-A tail also requires the use of more nucleotides to form the functional mRNA than that found on a corresponding bacterial mRNA molecule. The eukaryotic mRNA offers more opportunities to control gene expression because regulation could occur at the levels of transcription, capping, intron splicing, polyadenylation, and mRNA export from the nucleus. 14. The genetic code was deciphered by adding artificial mRNAs with specific nucleotide sequences to an artificial protein synthesis system. By analyzing the amino acid composition of the resulting polypeptides, researchers could connect specific nucleotide sequences to the genetic code. 15. Transposons would eventually lose the ability to replicate and jump between genes as they acquired mutations that would disrupt their transposable element functions.

16.

Refer also to Figure 13-23. RNA → (reverse transcriptase) → DNA. Your diagram should show that reverse transcriptase polymerizes the DNA strand in a 5' → 3' direction as it reads the RNA strand from a 3' → 5' direction. 17. If the irradiated fungus grows on all three media, then it does not have a mutation in a gene affecting its nutritional requirements. If it does not grow on any of the three media, its mutation is unknown, but it does not affect vitamin or amino acid biosynthesis. 18. Prokaryotes may have lost their introns early in evolution because the synthesis of intron-free mRNA may have conferred a selective advantage on the ancestral organisms, by supporting more rapid, energy-efficient growth.

Chapter 14

Checkpoint

14.1 • Regulation of transcription is the most efficient means of gene regulation in bacteria. • Prokaryotic gene regulation acts primarily through the control of transcription. Eukaryotic gene regulation can act at many different levels of gene expression such as control of transcription, and posttranscriptional mechanisms that include regulation of mRNA processing, nuclear export and stability, and controls of translation, protein activity, and protein stability. **14.2** • Promoter—RNA polymerase binding site; CAP binding site—binds catabolite activator protein when cells have insufficient supply of glucose; operator sequence—binding site for *lac* repressor protein; structural genes—encode enzymes and proteins that function in lactose metabolism. • The *trp* operon encodes a promoter, operator (repressor binding site), and structural genes as does the *lac* operon. • The *trp* operon is a repressible operon because it is usually turned “on” and is only repressed when the cells have sufficient levels of tryptophan; the *lac* operon is inducible because it is only activated when cells have an insufficient supply of glucose and are exposed to the sugar lactose. • Glucose is the preferred carbon source; cells sense glucose levels, and when they are low, cAMP is produced, activating the CAP protein, which binds near the lactose promoter to speed up transcription of the *lac* operon. **14.3** • Bacterial genes are primarily regulated through mechanisms that control the rate of transcription. Eukaryotic genes are regulated at many different levels of gene expression, including transcriptional, posttranscriptional, and

posttranslational controls. • Certain eukaryotic genes (e.g., ribosomal RNA genes, egg storage protein genes) that must produce high levels of their products in cells are present in multiple copies to provide high levels of RNA needed to produce high levels of their encoded product. • Chromosome structure affects the expression of eukaryotic genes by controlling its packing. Genes are inactivated in tightly packed and coiled chromosomes (e.g., heterochromatin). Active genes are associated with more loosely packed euchromatin. Chromosome packing is controlled through chemical modifications of histones and the methylation of DNA. • Alternate splicing can produce different proteins by removing or leaving intact some of the pre-mRNA molecule during the splicing process. Refer to Figure 14-15 in constructing your diagram. See also figure below.

• See Table 13-1 and Fig. 14-14.

Figure Questions

FIG. 14-2 If the *lac* repressor gene were deleted, the *lac* operon would be activated in the presence or absence of lactose. **FIG. 14-4** If the *trp* operator region were mutated or deleted, the operon would remain active in cells grown with high intracellular levels of tryptophan. **FIG. 14-5** If cAMP levels in

the mutant are low in the absence of glucose, transcription of the *lac* operon would be low or inactive in cells grown on lactose.

Test Your Understanding

1. a 2. c 3. c 4. b 5. c 6. e 7. a 8. c 9. a 10. c 11. c 12. (a) constitutive; (b) inducible; (c) repressible. 13. *Mutant a*: mutation lies within the *trp* operator; *mutant b*: mutation lies within the *trp* promoter; *mutant c*: mutation lies within the *trp* repressor coding sequence. 14. The data suggest that the deletion removed an enhancer sequence that interacts with the gene. 15. The repressor gene needs to be constitutively transcribed and not under the control of the *trp* operon. If it were under the control of the *trp* promoter, it might not be transcribed under repressed conditions. 16. Multiple levels of control probably evolved in eukaryotes due to cell differentiation and the long lifetimes of cells. A eukaryotic cell might encounter many different changes to physiological, metabolic, and nutritional states during its lifetime, requiring different regulatory mechanisms to respond to those changes. 17. Gene regulation is essential in all cells to ensure efficient growth and adaptability to environmental changes. Loss of an essential regulatory element would most likely result in the loss of selective advantage or death.

Chapter 15

Checkpoint

15.1 • 3' CCTAG ↓ G. • A researcher would clone the gene by RT-PCR from the mRNA produced. By cloning the gene from the mRNA from the liver tissue, the liver-specific form of the protein could be deduced from the nucleotide sequence of that cDNA. • PCR amplification allows one to specifically amplify the desired fragment of DNA to be inserted into a plasmid, whereas gene cloning requires sorting through many different clones to find the required gene.

15.2 •

• Inject the Cas9 protein and synthetic guide RNAs homologous to two regions in the target gene. The Cas9 endonuclease will cut the gene in two places. Repair systems within the cell will then relink the cut ends, creating a deleted region within the gene. • Inject the Cas9 protein, a donor DNA fragment containing the normal gene sequence, and guide RNAs that target cuts to the gene on either side of the mutated region. The Cas9 endonuclease will cut out the DNA region containing the point mutation. The gap in the chromosomal DNA will then be repaired by homologous repair systems using the normal sequence derived from the donor DNA. **15.3** • For qPCR analysis, the cDNAs of the gene of interest from each cell type are amplified by PCR using primers that flank that specific gene. The fluorescence from a probe that only binds to the amplified double-stranded DNAs are measured during each PCR cycle. The number of molecules of that specific mRNA in each sample can be calculated from the rate of increase of fluorescence with the number of PCR cycles. For a DNA chip, mRNAs from each cell type are copied as fluorescent-labeled cDNAs using different colors for each cell type. The two cDNA populations are incubated on a DNA chip containing dots of DNA fragments from each gene in the genome. The level of gene expression in the cells is determined by comparing the relative fluorescence intensity of the two colors found in each dot on the chip. RNA-seq analysis involves converting total cellular mRNAs into cDNAs, which are then subjected to high-speed DNA sequencing. Using computers to count and align cDNA sequences with previously sequenced genomic DNA, the relative numbers of the mRNAs per cell can be compared between the two cell types. • Identify your gene by comparing its sequence to data in the GenBank. Using your derived protein sequence data, search for similar proteins (or parts of your protein) in organisms in which their function is known. **15.4** • The gene might be involved in one of several different developmental functions relating to touch, including the development of touch receptor cells, or of nerve cells used to signal touch, or of muscle cells that might respond to the touch signals. **15.5** • The significant medical advantages of recombinant human insulin include the lack of allergic reactions that may be produced by insulin obtained from animal sources. • STRs are stretches of short DNA sequences repeated multiple times within the human genome. The number of repeated sequences in each region is highly variable among individuals. By measuring the number of repeated sequences in multiple STR regions, investigators can identify an individual

with a very high degree of probability. • Mice have many genes in common with humans. By using targeted gene modifications and mutagenesis of genes in mice that are also found in humans, investigators can gain insights into their functions and develop potential treatments for genetic disorders involving those genes. **15.6** • A gene drive is a locus that contains an endonuclease that is specific for a region on a host cell chromosome and a “cargo” gene that confers some new trait on the organism. Endonucleases encoded by the gene drive locus on one chromosome of a diploid organism will cut a region in its homologous chromosome. This can be repaired by incorporating the gene drive locus at that site, making the individual homozygous for the gene drive. When that individual mates with a wild-type organism, the heterozygote zygote is quickly converted to a homozygous gene drive individual, resulting in as much as a 100% transmission of the gene drive to the next generation. Under these conditions, the number of gene drive organisms in the population will continue to increase with each generation, spreading throughout the population. A gene drive may simply distribute some beneficial trait throughout a population. • A crash drive is engineered so that the cargo gene carries a lethal trait or one that causes sterility in the progeny, resulting in the extinction of the population after a number of generations. **15.7** • Environmental risks include the potential for genetically modified organisms to pass on engineered foreign genes to wild relatives or different species, causing unknown environmental problems, such as the production of “superweeds” from herbicide-resistant crops, or the harmful killing of useful insects from crops engineered to produce pesticides.

Figure Question

FIG. 15-14 Suspect 2's DNA matches the crime scene DNA.

Test Your Understanding

1. a 2. b 3. e 4. e 5. a 6. b 7. a 8. a 9. d 10. b 11. d 12. Many eukaryotic genes contain introns, which must be removed from pre-mRNAs. Bacterial cells do not have the spliceosomes required to remove introns and splice together exons to form functional mRNAs. Expressing eukaryotic genes in transgenic plants or animals allows functional mRNAs to be formed through processing by the host organism's splicing apparatus. 13. Knowledge of bacterial genetics led to the discovery of the enzymes, gene regulation mechanisms, and vector plasmids that were

used (and are still used) to develop DNA technology. We would not have been able to develop genetic engineering methods employed today without the information derived from the years of basic research into bacterial genetics. 14. Suspect 2's DNA matches the evidence. 15. The universality of genetic systems is strong support for the view that all organisms evolved from common ancestors. 16. DNA technologies used today have provided many advances in the fields of medicine, pharmaceuticals, agriculture, and criminal justice.

Chapter 16

Checkpoint

16.1 • Human karyotyping provides information about the chromosome composition of the individual. It can identify the existence of chromosome abnormalities such as extra or missing chromosomes, translocated parts of chromosomes, deletions, and inversions. • Pedigree analysis can assist in determining the pattern of inheritance of a specific trait; it complements karyotype analysis, which can identify chromosome abnormalities, and molecular genetic methods, which can identify specific types of mutations in affected genes. • Comparison of an individual's gene sequences with other sequences stored in gene databases can assist in identifying the specific mutations that are involved in a genetic disease. Comparative genome database information can also shed light on the specific function of an affected gene if the function of that gene is known in another organism. • Mice and humans share many genes that have common structures and functions. Comparing a human gene to a similar mouse gene with a known function can give insights into the function of its human counterpart. If the mouse gene's function is not known, genetic manipulation of the mouse gene (by mutation and observing the effect on the mouse's phenotype) can provide insights into function of the homologous human gene. **16.2** • Most cases of Down syndrome are produced by nondisjunction in meiosis associated with an extra chromosome 21. See figure below.

- Cri du chat syndrome involves a deletion in chromosome 5.
- Fragile X syndrome involves a weak region near the tip of an X chromosome, associated with many repeats of a CGG sequence that disrupts a gene involved in nerve cell function.
- Genomic imprinting is a form of epigenetic inheritance (see Chapter 14), usually due to methylation of specific regions of DNA within a chromosome. **16.3** • Phenylketonuria and Tay-Sachs diseases are autosomal recessive genetic diseases.
- Huntington's disease is inherited as an autosomal dominant trait.
- Hemophilia A is inherited as an X-linked recessive disease. **16.4** • Gene therapy is a strategy for treating genetic disease by introducing a normal, therapeutic allele into the individual, usually by employing a viral vector to move the allele into target cells. A potential concern is that the viral vectors might be toxic or trigger severe reactions by the patient's immune system. **16.5** • The advantages of amniocentesis, chorionic villus sampling, and preimplantation genetic diagnoses are that genetic diseases in the fetus can be detected during a pregnancy. Disadvantages are that none of these tests are foolproof. With amniocentesis, the results of the test are not obtained until well into the second trimester. Most of the conditions it detects are incurable, making it more difficult to safely terminate the pregnancy. Chorionic villus sampling results are obtained earlier, reducing those potential risks. Preimplantation diagnosis is not as accurate as the first two methods but is used to detect potential diseases in embryos prior to implantation. It is used for patients who have possible risk factors, allowing physicians to screen healthy embryos for implantation.
- The goals of genetic screening for newborns are to detect potential genetic diseases that can be addressed by early treatment of the disease. The goals of genetic screening in adults are to determine potential risk factors of having children with inherited diseases. **16.6** • Many different types of genetic disorders occur in all human populations. It would be incorrect to assume that certain individuals or populations carry most of the abnormal alleles.
- The incidence of autosomal recessive diseases depends on the frequency of the abnormal allele in the population. Each parent must contribute a recessive allele to produce

offspring with the disease. Parents who are closely related have a higher probability of each having the same abnormal allele, resulting in a higher risk of offspring who will develop that disease. • Health and life insurance companies base their insurance rates on the probability that an individual will be healthy or live to a certain age. If the companies knew that a person were harboring genes that might cause poor health or death at an early age, they would be in a position to refuse to insure that individual.

Figure Question

FIG. 16-4 An XY sperm would give rise to Klinefelter syndrome, a 0 sperm (no sex chromosome) would give rise to Turner syndrome, and a YY sperm would give rise to an XYY karyotype.

Test Your Understanding

1. e 2. c 3. e 4. a 5. d 6. c 7. e 8. a 9. d 10. e 11. a 12. (a) Test the potential parents for the Tay-Sachs allele. If both carry the recessive allele, perform preimplantation diagnosis for in vitro fertilization, or chorionic villi sampling during early pregnancy. (b) There is low risk of genetic disease if the young man is unaffected. (c) There is no significant risk of inheriting X-linked hemophilia A given that the young woman's male parent is unaffected. (d) Offer the young man testing for the Huntington's gene, particularly if he intends to have children. He should receive counseling regarding the implications for his own future, should he test positive. (e) There is a duty to respect the patient's wishes. Some would argue that there is a moral duty to advise the patient that she should inform the sons of her condition if they intend to have children before the mother's diagnosis is revealed to them. 13. Genes contribute to a large part of the physical makeup of the individual. Many types of disorders and behaviors, however, are complex and may have multiple genetic and environmental components. 14. Chromosome deletions usually result in the removal of many genes, whereas a frameshift mutation typically results in the shortening of some part of a single gene's product. If a small deletion were to occur within a specific gene, then the expression of that gene might be affected in a similar way to a frameshift mutation within the same gene. 15. It is likely that the approximately 500 identical DNA segments shared by mice and humans contain genetic information that is essential to both species and has been conserved in evolution.

Chapter 17

Checkpoint

17.1 • The principle of nuclear equivalence is demonstrated by the Steward, Gurdon, and Wilmot experiments that show that a differentiated cell nucleus can be reprogrammed to support the development of an organism to adulthood. This

demonstrates that the genes in a differentiated cell nucleus are equivalent to the genes found in embryonic cells. • Wilmot's team recognized that the embryonic nucleus was arrested in metaphase II of meiosis, whereas the donor cell for the adult nucleus is usually in the middle of the S phase of the cell cycle. By withholding nutrients, the group was able to force the donor cells into the G₀ state, synchronizing the cell cycles of the donor nucleus and the egg cytoplasm. • Induced pluripotent stem cells are produced from differentiated cells by reactivating genes that are "locked" in an inactive state during development through epigenetic changes involving DNA methylation, histone modifications, and the production of inhibitory microRNAs. The ability to activate genes that can convert differentiated cells to pluripotent cells supports the principle of nuclear equivalence because it demonstrates that these genes have not been lost or irreparably altered during the differentiation process. **17.2** • *Drosophila* development involves an anterior–posterior body plan that is found in many invertebrates and vertebrates. *C. elegans* has a rigid developmental plan and transparent cells that allow investigators to follow the lineage of every somatic cell. Both *Drosophila* and *C. elegans* have short life cycles and are genetically well characterized, facilitating the isolation and analysis of developmental mutations. Many genes affecting the development of multicellular organisms were first discovered with *Drosophila*. *Arabidopsis* is a small, fast-growing plant with a small genome used to study development in plants. *M. musculus* is a model organism for studying development in mammals, including humans. It has a short lifespan compared to other mammals, it is easily raised in captivity, and methods have been developed for the production and analysis of strains with developmental mutations. • Transcription factors control the activity of genes. They influence development by activating genes required for the differentiation of specific cells. • Induction involves developmental interactions between cells in which specific cells signal other cells to organize into specialized structures. • Apoptosis refers to programmed cell death. For example, during development, certain cells in budding appendages may be programmed to die, forming fingers. **17.3** • Oncogenes are typically growth-activating genes that produce continuous, abnormal growth when the control of their expression is altered. Tumor suppressor genes normally prevent cells from undergoing inappropriate growth and cell division. In cancer cells tumor suppressor genes are inactivated. • When reprogrammed cells interact with older surrounding cells, they may develop as tumors. The use of highly expressed transcription factors that are coded for by oncogenes may contribute to this effect if their expression remains at high levels in the reprogrammed cells.

Figure Questions

FIG. 17-1 Vertebrate organs can contain cells derived from more than one lineage. For example, the cortex of the adrenal gland is derived from mesoderm and the medulla is derived

from ectoderm. **FIG. 17-2** Only some of the undifferentiated cells from the root discs produced plantlets, suggesting that not all differentiated plant cells are totipotent. **FIG. 17-3** The egg nucleus would be haploid and it is not clear that it would play a role in the development of the tadpole. If the nucleus in the unfertilized egg had not been killed, one could argue that the development of the adult frog may have proceeded from the activation of genes in the egg nucleus, rather than those of the differentiated intestinal cell nucleus. It would not be possible to clearly interpret the results from that experiment. **FIG. 17-4** The egg nucleus was haploid; the nucleus from the cultured mammary cell was diploid. **FIG. 17-13** *Hox* genes that are active in the mouse, but not in *Drosophila*, are genes 3, 10, 11, 12, and 13. **FIG. 17-15** Germ line cells in *C. elegans* do not give rise to other types of cells in the individual. They give rise to gametes. Zygotes produced from the fusion of gametes, however, give rise to all of the different cell types in a new individual.

Test Your Understanding

1. c 2. d 3. b 4. c 5. d 6. c 7. b 8. d 9. c 10. a 11. b 12. e 13. Almost all developmental processes are controlled through mechanisms that regulate some aspect of gene expression. Specific sets of genes are activated or inactivated during development. Many developmental genes code for transcription factors. 14. Each model organism provides specific characteristics suitable for the efficient analysis of different types of developmental processes. Most have well-characterized genetic systems and short life cycles, allowing for the isolation of many different types of mutant strains affecting development. 15. A number of genes responsible for the production and maintenance of stem cells are proto-oncogenes that code for transcription factors. Inappropriate expression of these genes causes them to become cancer-driving oncogenes. 16. Many genes involved in the development of *Drosophila* and *C. elegans* also control development in mammals. The common chromosomal organization and function of *Hox* genes in almost all animals with an anterior–posterior axis is a strong argument that modern organisms evolved from a common ancestor. 17. Evo Devo argues that developmental genes (such as the *Hox* genes) that are common in both structure and function represent “molecular fossils” that are important drivers of evolutionary change. The occurrence of mutations in these genes can lead to dramatic morphological changes. This could explain how a new species with a different body plan could rapidly evolve. 18. The resulting flowers will consist of sepals and carpels.

Chapter 18

Checkpoint

18.1 • Microevolution is the accumulation of small genetic changes in a population; macroevolution involves greater genetic changes, such as those leading to an ancestral popula-

tion giving rise to a new species. • Evolution involves aggregate genetic changes that occur among organisms in a population over generations, not the changes that may occur in a particular individual during its life. **18.2** • Aristotle visualized organisms changing over time. His ideas differed from modern evolutionary theory because he did not propose any type of natural process to explain these changes and he envisioned changes as a progression or a “scale of nature” in which organisms became more perfect. • Darwin proposed natural selection as the mechanism for evolution; Lamarck’s explanation invoked a type of “vital force” that drove organisms to change to become more adapted to their environment during their lifetimes and to pass these adaptations to their descendants. **18.3** • Darwin invoked the well-recognized power of artificial selection in the breeding of new varieties of plants and animals as the basis for his explanation of evolution by natural selection. • Variations that cannot be transmitted to offspring are a dead end and cannot play a role in evolution. • Although Darwin recognized that evolution required natural selection acting on heritable variation in populations, he did not know the mechanism of inheritance. The modern synthesis couples Mendel’s explanation of inheritance with an understanding of the genetics of populations. **18.4** • Scientists usually date fossils through comparisons of the sedimentary rock layers in which they are found. • *Mesosaurus* lived prior to the separation of southern Africa and South America by continental drift. • Homologous features are evidence that two groups share a common ancestor. Homoplastic features, which are superficially similar because they are used in similar ways, are evidence of convergent evolution. • In addition to common embryonic morphology among vertebrates, genetic studies (as discussed in Chapter 17) provide strong evidence that evolution builds on pre-existing developmental patterns. • Researchers moved populations of guppies from a high-predation habitat (in which there is natural selection against larger guppies) to a low-predation habitat (in which such selection was absent). Eighteen generations later, they were able to demonstrate heritable changes in the relocated populations such that the guppies matured at a larger size compared to their ancestral population.

Figure Questions

FIG. 18-11 Northwest coast of Europe. **FIG. 18-12** Australia. **FIG. 18-19** Hippopotamuses. **FIG. 18-21** You might predict that larger predators introduced into the low-predation habitat would convert it to a high-predation habitat in which there would be natural selection against larger guppies. The expected result might be heritable changes in the population, causing the guppies of future generations to mature at a smaller size on average. Can you think of alternative predictions?

Test Your Understanding

1. d 2. b 3. c 4. c 5. b 6. d 7. e 8. b 9. b 10. b 11. Changes that affect developmental patterns. 12. Comparative anatomy; molecular comparisons (including proteins as well as the virtual

universality of the genetic code); common developmental patterns and their genetic basis. 13. Darwin meant that a species that possesses heritable variation enabling it to adapt to new challenges is most likely to survive (and reproduce). 14. (a) Natural selection can only work in the present; it cannot anticipate the future. (b) Evolution results from natural selection acting on heritable variation within a population. Although individuals do not themselves evolve, the genetic makeup of the population over time will be influenced by the contributions of individuals possessing heritable characteristics that cause them to be more likely to survive and produce offspring that exhibit those same characteristics. (c) Every organism is a descendant, but not every individual organism becomes an ancestor. Every individual alive today exists because every single one of its direct ancestors in the entire history of life on planet Earth survived long enough to reproduce. (d) Replacement of a single nucleotide can result in the replacement of one amino acid by another, with the potential of producing an altered protein. The new protein may be nonfunctional, or it may possess novel functions. Single nucleotide changes affecting RNAs, particularly those with regulatory functions, may have even greater evolutionary significance. (e) Genetic changes in a population over time constitute microevolution. 15. The information that “limbless” salamanders occupy similar habitats (shallow water) is a clue that limblessness may have been selected as an adaptation to this particular environment. Think about the kinds of additional information that would help you answer this question more fully. For example: Are there any limbed salamanders that occupy the same habitats? If so, do they have special adaptations? Do the limbless salamanders have any close relatives (perhaps as identified by molecular analysis) that have limbs? If so, what types of habitats do they occupy? 16. Tarsier. 17. Those individuals in a pest population that are genetically resistant to a particular pesticide are more likely to survive exposure and pass on their genes for resistance to their offspring. If exposure to the pesticide continues, there will also be selection for any additional new genes for resistance that may arise through mutations. Therefore, over time the population will consist of a higher proportion of resistant individuals, rendering the pesticide much less effective.

Chapter 19

Checkpoint

19.1 ● Populations. ● No. ● Frequency of $T = 0.6$. **19.2** ● $T = 0.6$; $t = 0.4$; $TT = 0.36$; $Tt = 0.48$. ● $A = 0.8$; $a = 0.2$; $AA = 0.64$; $Aa = 0.32$; $aa = 0.04$. ● No. The genotype frequencies clearly do not match Hardy–Weinberg expectations. **19.3** ● Natural selection. ● Mutation is the source of new genetic variation in a population. ● Mutation and gene flow are associated with an increase in variation within a population. Populations diverge genetically due to such forces as nonrandom mating, genetic drift, and differences in natural selection. ● Stabilizing selection favoring a heterozygous genotype as well as disruptive selection against a heterozygous genotype can change genotype frequencies without changing allele frequencies. Alleles will be maintained in the favored genotypes. **19.4** ● There is strong selection against individuals with sickle cell anemia (homozygous recessive). In regions where malaria is a problem, the sickle cell allele is maintained in the population because it confers resistance to malaria on heterozygous persons (relative to homozygous individuals with normal hemoglobin). ● Frequency-dependent selection tends to maintain genetic variation within a population over time. ● Researchers can test the genetic basis for clinal variation by conducting studies similar to those of Clausen, Keck, and Hiesey (see Fig. 19-9).

Figure Questions

FIG. 19-2 40 mice. **FIG. 19-4** The relationship between wing color and antenna length is unknown, so selection for antenna length would be impossible to predict. **FIG. 19-8** $a = 0.7$; $A = 0.3$.

Test Your Understanding

1. b 2. b 3. b 4. b 5. b 6. c 7. a 8. e 9. b 10. c 11. d

12. See figure below.

Compare your graphs to those in Figure 19-4. 13. Mutations are the source of all new genetic variation. 14. Natural selection acts on individuals, each of which has a particular phenotype. That phenotype is determined partly by the genotype, so selection on the genotype is indirect. 15. Compared to the United States, the populations of Finland and Iceland are genetically much more homogeneous and occupy more similar environments. This relative lack of variability makes it much easier for researchers to analyze their data and draw meaningful conclusions. 16. The phrase “survival of the fittest” has become a poor way to think about evolution because it is widely misinterpreted by nonscientists. Evolutionary biologists think about fitness in terms of reproductive success in response to selective forces. 17. Amish population: 4.9 out of 1000; general population: 1.0 out of 1 million. 18. If due to genetic factors, the differences in average weights observed in the natural populations would be similar in the aquarium-raised populations. 19. New information on genetic polymorphism in humans will be useful in understanding the genetic basis of various diseases, with the expectation that new therapeutic approaches may follow. However, this information will be challenging, particularly to individuals, because risk estimates may not be accompanied by useful recommendations and may even create needless worry.

Chapter 20

Checkpoint

20.1 • The members of a biological species interbreed in nature to produce fertile offspring, but do not interbreed with other species. • The biological species concept does not work well for extinct species, asexually reproducing species, or species in captivity. • A population that meets all the criteria of the biological species concept shares a common gene pool. To the extent that various morphological characteristics are genetically determined, the population is likely to meet the definition of a morphological species. **20.2** • Wood frogs and leopard frogs breed at different times (temporal isolation). They are also subject to behavioral isolation because males use different vocalizations to attract mates. • Temporal isolation involves breeding at different times; behavioral isolation, also known as sexual isolation, is based on differences in reproductive behaviors. • Mechanical isolation is based on differences in reproductive structures. In gametic isolation, incompatibilities between eggs and sperm prevent fertilization. • Hybrid sterility. **20.3** • Mountains, glaciers, rivers, canyons, land barriers, deserts, etc. • Individuals produced by allopolyploidy (hybridization followed by polyploidy) are reproductively isolated. They can form a new species because they can only reproduce with themselves (if self-fertilizing) or with each other, and not with individuals of the two parent species. • Pupfishes: allopatric speciation among isolated springs; cichlids: sympatric speciation

within individual lakes. **20.4** • Phyletic gradualism and punctuated equilibrium are not mutually exclusive. Periods of phyletic gradualism, stasis, and rapid evolutionary change can all occur in the course of the evolution of a particular group. **20.5** • The large-scale phenotypic changes that occur when pre-existing structures become modified as evolutionary novelties are associated with the evolution of new species and higher taxa (macroevolution). • The modification of a pre-existing structure (a preadaptation) can occur through relatively minor changes in genetic regulation, thereby quickening the pace of macroevolution. • Paedomorphosis allows a species to occupy a particular habitat for the entire lifespan, without competition from adults of related species. • Mass extinction leaves many ecological niches available to the surviving species. Adaptive radiation may occur as these species evolve to utilize these now unoccupied habitats.

Figure Questions

FIG. 20-9 The $2n = 10$ hybrids would produce $n = 5$ gametes. It is unlikely that it could produce fertile offspring crossed with either species A ($n = 3$ gametes) or species B ($n = 2$ gametes). **FIG. 20-13** Your hypothesis would be supported if the F_1 hybrid females were found to choose red and blue males with equal frequency in well-lit aquaria. **FIG. 20-15** Long-term environmental stability, such as that observed in tropical rain forests, is usually associated with phyletic gradualism. **FIG. 20-18** Future adaptive radiation in the Hawaiian honeycreepers (if it occurs at all) will likely be restricted to human-created habitats because traditional natural habitats are disappearing.

Test Your Understanding

1. a 2. a 3. c 4. d 5. b 6. c 7. b 8. e 9. c 10. d

Also compare your diagrams with Figure 20-9. The F_1 hybrid ($2n = 9$) is unlikely to be fertile. However, if the chromosome number is doubled ($2n = 18$), it is likely that the hybrid could produce $n = 9$ gametes. It would be able to breed with other such hybrids, but not with either of the two parental species. 12. If the original isolated population is small, it could become extinct. However, if it survives it is more likely to diverge genetically from the parent population due to genetic drift and the founder effect. 13. In one sense hawthorn maggot flies and apple maggot flies can be considered an example of speciation that originated through positive assortative mating because they are reproductively isolated by their mate choice behaviors. 14. The human-caused mass extinction that is occurring today may be on a scale that is unprecedented in geological history and many of the potential effects on the future of the human population are unpredictable. 15. April 1 is the only date (of those given) in which both populations are within their breeding season.

Chapter 21

Checkpoint

21.1 • The origin of life required a reducing atmosphere (i.e., the virtual absence of free molecular oxygen) because of oxygen's reactive and destructive properties. Chemical sources of important elements (particularly carbon, hydrogen, oxygen, and nitrogen) were needed along with energy to power chemical reactions. Time was the fourth requirement, although not as much time as one might think because there is evidence that life arose early in the history of the planet. • According to the prebiotic soup hypothesis, life arose on or close to Earth's surface; the iron-sulfur world hypothesis envisions life originating from molecules produced in hydrothermal vents on the ocean floor. Both hypotheses seek to explain how life could have arisen as the chemical reactions of simple molecules led to greater complexity. **21.2** • Major steps that probably occurred in the origin of cells were the evolution of simple metabolism with an energy source and occurring within a boundary, as well as the evolution of molecular reproduction. • Molecular oxygen (produced by photosynthetic cyanobacteria) increased slowly in the atmosphere. Eventually oxygen rose to levels that poisoned anaerobic organisms but also provided conditions for the evolution of aerobes.

Also compare your sketch to Figure 21-8. **21.3** • Prokaryotic cells → eukaryotic cells → multicellular organisms • Fishes → amphibians → reptiles → mammals • Ferns → gymnosperms → flowering plants.

Figure Questions

FIG. 21-2 There would have been no source of carbon for organic molecules if methane had been omitted in the experiment. **FIG. 21-5** Without mutations, the selective process would have had nothing to act upon. **FIG. 21-7** The chemical reactions that destroy ozone cause this protective layer to be less effective in screening out ultraviolet radiation, which is harmful to most organisms.

Test Your Understanding

1. a 2. b 3. c 4. c 5. e 6. c 7. a 8. a 9. b 10. b 11. c 12. c 13. There was little or no molecular oxygen for aerobic metabolism in bacteria prior to the evolution of oxygen-producing photosynthetic bacteria. 14. Keep in mind that life requires metabolism as well as self-replication. 15. A successful experiment such as

the one described would be a demonstration that the origin of life could have occurred through chemical evolution but would not constitute proof. 16. Molecular oxygen (produced by photosynthesis) is the basis for aerobic metabolism. In contrast to anaerobic metabolism, aerobic metabolism makes large amounts of energy available to organisms (see Chapter 8), enabling them to grow to much larger sizes. 17. One hypothesis could be that the molecular fossils (in the form of lipids) were not actually produced by cyanobacteria and therefore do not provide an accurate date for their early presence. An opposing hypothesis might be that cyanobacteria evolved at the early date (2.7 bya), but conditions for formation of structural fossils did not exist or that such fossils are yet to be found. Similarly, one might hypothesize that over 700 million years were required for their numbers to reach a level at which structural fossils would have been reliably produced.

Chapter 22

Checkpoint

22.1 • Opposable thumb (and possibly big toe); highly flexible digits with fleshy pads at the ends and nails instead of claws. • Eyes positioned at the front of the head. **22.2** • Suborder Prosimii; suborder Tarsiiformes; suborder Anthropoidea. • Monkeys possess tails, which hominoids (apes and humans) lack. **22.3** • The foramen magnum of an ape is situated in the rear of the skull; that of the human is located in the skull base. Unlike modern humans, apes have pronounced supra-orbital ridges. The ape jaw is relatively rectangular compared to the more U-shaped jaw of humans. • The human skeleton exhibits multiple adaptations for bipedal posture, including complex curvature of the spine (in contrast to the simply curved ape spine), a pelvis that is shorter and broader than that of an ape, and alignment of all the toes (unlike the opposable big toe of many apes). • Members of genus *Homo* are distinguished from the australopithecines by larger brains, smaller premolars and molars, and evidence of tool use. • *H. erectus* had a larger brain than *H. habilis*, was taller, and made more sophisticated tools. • Compared to *H. sapiens*, *H. neanderthalensis* had larger brains and sturdier builds. They also possessed heavy supra-orbital ridges, which are lacking in *H. sapiens*. **22.4** • Early human societies consisted of nomadic hunters and gatherers. Agriculture began with the cultivation of plants around 10,000 years ago, which was usually followed by the domestication of animals. Agriculture freed much of the population from the need to produce food, fostering the cultural evolution that led to the industrial society in which we live today. Not all human societies have gone through these transitions in this way.

Figure Questions

FIG. 22-1 Gorilla. **FIG. 22-2** Gorillas. **FIG. 22-9** Consider the following in placing *Homo floresiensis* and the Denisovans in the chart: The researchers who have been most involved in studies of *H. floresiensis* fossils think that it was an evolutionary offshoot of *H. erectus* that existed from 700,000 to at least 60,000 years ago. Based on fossil dating and molecular evidence, the Denisovans are currently thought to represent a sister group of *H. neanderthalensis*, existing as recently as 50,000 years ago (and possibly as early as 80,000 years ago).

Test Your Understanding

1. c 2. a 3. a 4. b 5. e 6. a 7. b 8. b 9. d 10. c 11. c 12. e 13. Scientists have found Neanderthal bones in Europe showing signs of cannibalism and dating from a time when no modern humans were present in that region. You might look for caves with evidence of occupation by *H. sapiens* and Neanderthals at close to the same time. Evidence of violent injuries to the Neanderthal remains, but not the *H. sapiens* remains, would possibly implicate modern humans in the Neanderthals' demise. The evidence would be stronger if the injuries could be shown to differ from the types of injuries Neanderthals have been implicated in inflicting on their own species. 14. Climate change since the last Ice Age has altered the range of reindeer. Humans are an extremely adaptable species, able to live in a wide variety of habitats. 15. Chimpanzees and humans did not exist at the time their lineages are thought to have diverged about 4 million years ago; therefore, their as yet undiscovered most recent common ancestor was a hominoid that was neither a chimpanzee nor a human. 16. As you form your opinion, consider the concept of fitness (both direct fitness and inclusive fitness) as understood by evolutionary biologists today. Do these ideas correspond to popular notions of "survival of the fittest"? Does natural selection apply to humans? Do you think artificial selection plays any role? Do you think that your ideas regarding future human evolution will be influenced by new information regarding the human genome?

Your cladogram should show *Ardipithecus* giving rise to *Australopithecus*, which in turn gave rise to *Homo*. You would not include the genus *Paranthropus* because there is no evidence that it was ancestral to *Homo*. 18. (a) African; (b) first migrants out of Africa; (c) Eurasian; (d) Amerindian (native Americans).

Chapter 23

Checkpoint

23.1 • *Amanita phalloides*. • The categories range from species to domain; three domains are currently recognized; as you move up the hierarchy, each taxon is more inclusive than the one below it. • Domain, kingdom, phylum, class, order, family, genus, species. **23.2** • Archaea (archaeons) belong to domain Archaea; bacteria belong to domain Bacteria; protists, plants, fungi, and animals belong to domain Eukarya; white willow belongs to domain Eukarya, kingdom Plantae; *Escherichia coli* belongs to domain Bacteria, kingdom Bacteria; tapeworms belong to domain Eukarya, kingdom Animalia; black bread mold belongs to domain Eukarya, kingdom Fungi. • Each node in a cladogram represents the splitting of two or more new groups from a common ancestor; each node represents the most recent common ancestor of each clade, which is represented by branches; and the branches diverging from a node share a set of characteristics. • In vertical gene transfer, genes are transmitted from parent to offspring within the same species; in horizontal gene transfer, genes are exchanged laterally among members of the same taxonomic group, for example, among bacteria by conjugation, or between members of different taxonomic groups, for example, between bacteria and archaea. **23.3** • Shared ancestral characters are characteristics that were present in an ancestral group and remain present in all groups descended from that ancestor; shared derived characters were present in a recent common ancestor and are present in its descendants; homology refers to traits organisms share as a result of their shared ancestry. • Shared ancestral characters are present in all groups descended from a particular ancestor. For example, all mammals have hair, so hair does not help us distinguish between carnivores and marsupials (e.g., kangaroos). However, shared derived characters of marsupials separate them from carnivores. For example, marsupial young are born at an immature stage and complete their development in the mother's pouch. • Molecular biology is helping systematists establish evolutionary relationships. The more similar the macromolecules of various groups of organisms, the more closely

related the species are considered to be. • A monophyletic taxon includes an ancestral species and all of its descendants. **23.4** • Systematists use shared derived characters to determine monophyletic groups. • Outgroup analysis is a research method used for estimating which features are shared derived characters in a group of organisms. • In applying the principle of parsimony, systematists select the simplest explanation to interpret the data. **23.5** • Modern systematics helps researchers understand the relationships and origins of viruses and other pathogens; this information helps health professionals understand the source and spread of infections, and leads to the development of prevention and treatment methods.

Figure Questions

FIG. 23-2 The Archaea are more closely related to the Eukarya; they share a common ancestor as indicated by node B. **FIG. 23-6** The coyote. **FIG. 23-7** Taxa 4, 5, and 6.

Test Your Understanding

1. a 2. e 3. c 4. a 5. c 6. c 7. e 8. a 9. d 10. Shared derived characters; molecular data. 11. Domains have been determined based on molecular data and cladistic analyses; historically, animals were assigned to kingdoms less rigorously; for example, systematists have determined that the protists are not a monophyletic group and now assign them to several "supergroups." 12. They are similar because they share a common ancestor. 13. Suggests archaea are more closely related to eukaryotes than to bacteria; such data suggests that archaea and eukaryotes share a common ancestor. 14. Figure 23-7a without branch 4 has similar branching; mosses would be represented by branch 1; horsetails and ferns by branches 2 and 3; and gymnosperms and angiosperms by branches 5 and 6.

15. Paraphyletic; monophyletic; polyphyletic.

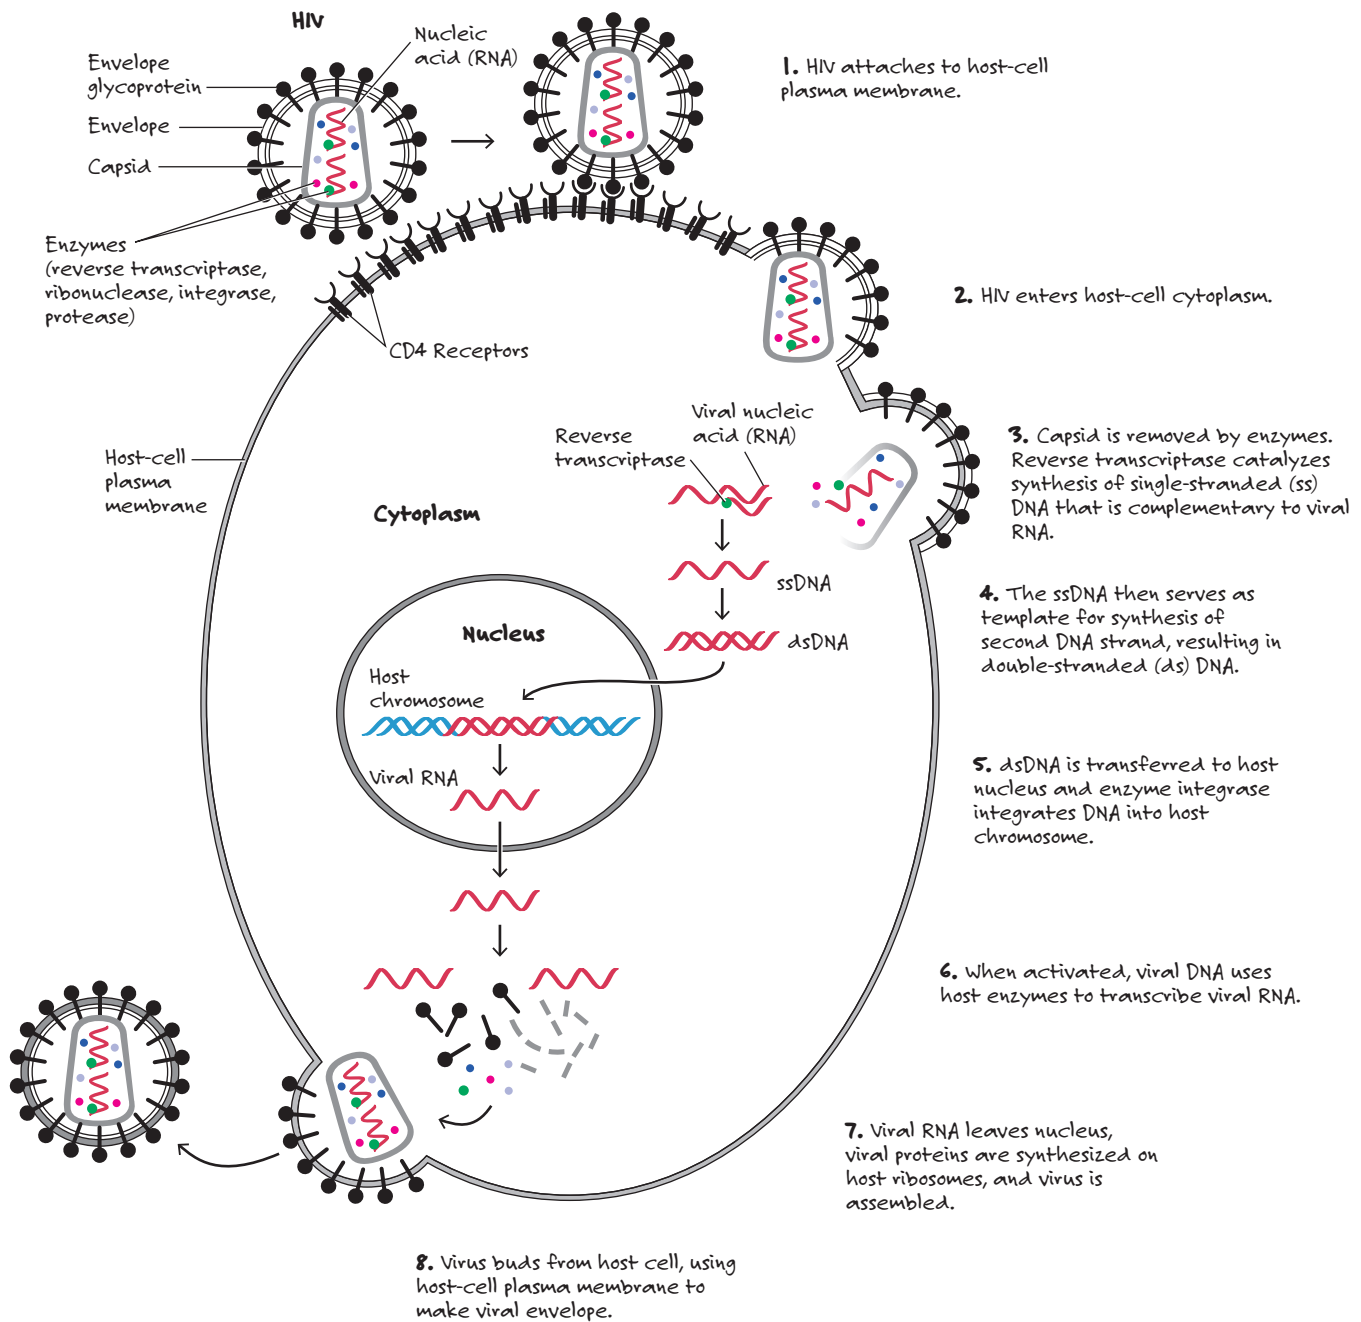

Chapter 24

Checkpoint

24.1 • Viruses are not cellular and cannot reproduce without a host; they lack the enzymes and other proteins needed to carry on cellular respiration and other metabolic activities; most viruses lack the components necessary to synthesize proteins. • A virus consists of a core of nucleic acid surrounded by a capsid made of protein subunits. Many viruses are surrounded by an envelope external to the capsid. **24.2** • Viruses can be classified based on their home range (the type of host species the virus can infect), on the type of nucleic acid (DNA or RNA) the virus contains, and whether its nucleic acid is single stranded or double stranded. They can also be classified based on size, shape, and presence of an envelope. **24.3** • Steps in a lytic cycle include attachment, penetration, replication and synthesis, assembly, and release. See figure at right; also compare to Fig. 24-3.

• In a lysogenic cycle, a temperate virus integrates into the host DNA. In contrast to a lytic cycle, the host is not immediately destroyed. **24.4** • Viruses can enter plants through damaged cells. Viruses can be transmitted from one plant generation to the next through infected seeds or by asexual reproduction. • Some viruses enter animal cells by fusing with the cell's plasma membrane; the entire virus, including the capsid, is released into the animal cell. Other viruses enter by endocytosis.

See also Fig. 24-7. • Viruses could have evolved from free-living complex cellular ancestors. Later, they became parasitic and, through time, lost some of the genes needed for protein synthesis and other cellular activities. • Polydnnaviruses do not have genes for making the proteins needed to replicate and produce new viruses. Genes needed for viral replication are found in the wasp genome; the viruses can replicate only in the wasp ovary cells. The wasp injects polydnnaviruses along with her eggs into certain caterpillars. These viruses express toxins that interfere with the caterpillar's immune defenses and development. This

action allows the wasp eggs to hatch and develop inside the caterpillar. The young wasps feed on the caterpillar. 24.6 • Both viroids and prions are subviral agents; they are smaller and simpler than viruses. Viroids consist of a very short, circular, single strand of naked RNA; they do not have a protective protein coat or proteins to assist in duplication. Viroids mainly infect plants. In contrast, prions are misfolded proteins. They arise spontaneously, mostly as a result of mutation. Prions apparently can aggregate and accumulate in the brain and in certain other tissues where they cause serious damage.

Figure Questions

FIG. 24-3 No, because the parts of the phage function together. The tail has proteins that recognize and bind to the host cell. The capsid surrounds and protects phage DNA. **FIG. 24-4** By integrating into the bacterial genome, the virus is reproduced in all of the cell's daughter cells for, potentially, many generations. In this way, the virus population is expanded and disseminated. **FIG. 24-6** The cytoplasm contains the materials and organelles necessary to synthesize proteins needed by the new viruses. Also glycoproteins must be transported to the cell membrane in order to envelope new viruses before release. **FIG. 24-7** The infected cells replicate, producing daughter cells with integrated proviral DNA. These daughter cells continue to transcribe the proviral DNA and bud new viruses. **FIG. 24-8** The caterpillar population would increase; the wasp population would decrease; the virus could become extinct because it would no longer have wasps in which to reproduce.

Test Your Understanding

1. e 2. a 3. b 4. a 5. c 6. e 7. b 8. b 9. c 10. c

11.

Release of viruses from host cell; see also Fig. 24-3a, step 5. 12. Viral genomes are single stranded or double stranded and can be DNA or RNA. 13. Neither has a protective coat; viroids have no proteins; prions have no nucleic acid 14. Polydnaviruses are mutualistic partners with certain wasps. Their relationship is so complex that it is likely they coevolved. Researchers have concluded that the polydnavirus evolved from a nudivirus that infected wasps millions of years ago. In time, the virus genome became incorporated into the wasp genome. Proteins needed for viral replication are now part of the wasp's DNA, and the virus can replicate only in the wasp's ovaries. 15. The progressive (escape) hypothesis holds that viruses originated as mobile genetic elements that escaped from one cell and entered another cell through damaged cell membranes. The regressive hypothesis is supported by discovery of giant viruses. Viruses may have evolved from complex, cellular, free-living ancestors. Later, they became parasitic and through time, lost some of the genes needed for protein synthesis and other cellular activities. According to the virus-first hypothesis, viruses predated or coevolved with their current cellular hosts. 16. Influenza viruses mutate frequently, necessitating ongoing development of new vaccines. The latest advances in nucleic acid technology must be applied to meet this challenge.

Chapter 25

Checkpoint

25.1 • Prokaryotes are exclusively single-celled organisms that, in contrast to eukaryotic cells, do not have membrane-enclosed organelles; most have a cell wall that surrounds the plasma membrane, and most have a single, circular DNA molecule instead of linear DNA. Bacteria and archaea differ genetically, in their chemical composition, and anatomically. Unlike archaea, bacteria contain peptidoglycan in their cell walls and can form endospores. • The cell walls of gram-positive bacteria are very thick and consist primarily of peptidoglycan, while the cell walls of gram-negative bacteria have two layers: a thin peptidoglycan layer and a thick outer membrane containing polysaccharides bonded to lipids. Distinguishing between gram-positive and gram-negative bacteria is important for treating certain diseases. For example, penicillin interferes with peptidoglycan synthesis and weakens cell walls of gram-positive bacteria. • Bacterial and eukaryotic flagella are different in structure, mechanism of propulsion, and protein composition. **25.2** • Prokaryotes reproduce asexually by binary fission, budding, or fragmentation. Gene transfer among prokaryotes takes place by three different mechanisms: transformation, transduction, and conjugation. • Transduction contributes to the rapid evolution of bacterial populations through horizontal gene transfer. The transferred bacterial chromosome becomes a recombination of its own original DNA and the DNA from another bacterium. This DNA is different, allowing diversification and adaptation.

The steps that take place during conjugation can also be found in Figure 25-8. **25.3** • Chemoheterotrophs obtain energy from organic molecules. • Facultative anaerobes use oxygen for cellular respiration if it is available, but can metabolize anaerobically when necessary. Obligate anaerobes carry out anaerobic respiration using terminal electron acceptors other than oxygen. Some obligate anaerobes are killed by even low concentrations of oxygen. Facultative anaerobes differ from aerobes because they do not require oxygen to carry out cellular respiration. • Prokaryotes obtain nitrogen needed to produce amino acids and nucleic acids by nitrogen fixation in which atmospheric nitrogen is reduced to ammonia. **25.4** • The archaeans were once thought to inhabit only extreme environments, such as hydrothermal vents and springs, extreme salt water, and oxygen-free environments. Scientists now think archaea may be found everywhere other organisms live. Methanogens produce methane from simple carbon compounds and inhabit oxygen-free environments in sewage, swamps, and the digestive tracts of humans and other animals. Methanogens are important in recycling components of organic products of organisms that inhabit swamps; the methane they produce is a greenhouse gas. • See Table 25-3. **25.5** • Bacteria form three types of symbiotic relationships with other organisms: mutualism, commensalism, and parasitism. • Biofilms are common along surfaces in aquatic environments and are also found on teeth, contact lenses, pipelines, catheters, and surgical implants. Biofilms consist of many species of bacteria, archaea, fungi, and protists. • Chemoheterotrophs break down dead organisms and waste to their organic components, which recycles nitrogen, oxygen, carbon, phosphorus, and other minerals. Many prokaryotes are important parts of biogeochemical cycles. Cyanobacteria fix carbon dioxide and generate oxygen. • Bioremediation is the process of using microorganisms (and sometimes other organisms) to detoxify or remove oil, gasoline, and other pollutants or toxic chemicals from the environment. The microorganisms break down certain toxins, leaving behind harmless metabolic byproducts. **25.6** • Koch's postulates are important because they help medical scientists determine whether a specific pathogen causes specific disease symptoms. • Exotoxins are strong poisons produced by bacteria that are either secreted from the cell or leak out when the bacterial cell is destroyed. Endotoxins are components of the cell walls of most gram-negative bacteria; they affect the host only after they are released when the bacteria die. Exotoxins cause specific symptoms and are destroyed by heating; endotoxins affect the entire body by binding to macrophages of the immune system and are not destroyed by heat.

Figure Questions

FIG. 25-2 A nucleus might be an unnecessary organelle that could interfere with or slow replication, causing prokaryotes to lose their advantage of rapid replication. **FIG. 25-8** The F plasmid contains the genetic information for making a sex

pilus. Each time an F plasmid is transferred to another cell, that recipient cell can then produce a sex pilus; genetic recombination increases.

Test Your Understanding

1. d 2. b 3. b 4. a 5. a 6. c 7. e 8. d 9. e 10. a 11. a

See also Fig. 25-2. 13. Characteristics of archaea are no peptidoglycan in their cell walls, plasma membranes with branched-chain hydrocarbons (synthesized from isoprene units) bonded to glycerol by ether linkages, and flagella structurally different from bacteria. 14. Eukaryotes depend on prokaryotes to make up their microbiota. Also, consider the ecological and industrial roles prokaryotes play. 15. Antibiotics impose selective pressure on bacteria by killing susceptible bacteria and leaving those that are resistant to pass on their genes for antibiotic resistance to future generations of bacteria. 16. The public would need to be educated about how to properly take prescribed antibiotics so that they are not contributing to the problem of antibiotic resistance. Society would need to fund research and support the development of new antibiotics.

Chapter 26

Checkpoint

26.1 • Protists may be photoautotrophic or heterotrophic (obtaining nutrition by absorption or by ingestion). • Protists that are not free living may be involved in symbiotic relationships with other organisms (ranging from mutualism, to commensalism, to parasitism). **26.2** • The structure of chloroplasts in different groups of eukaryotes (some with two external membranes and others with three) is evidence that chloroplasts

arose through several endosymbiotic events. These events began with primary endosymbiosis of ancient cyanobacteria and continued with subsequent secondary endosymbiosis in some evolutionary lines. • The various groups informally called protists differ widely in their ultrastructural features and molecular composition. These differences are strong evidence that, as a group, the protists do not include all the descendants of a common eukaryote ancestor; hence, they are a paraphyletic group. 26.3 • The mitochondria of excavates are atypical. • Diplomonads include *Giardia intestinalis*, which causes severe diarrhea. *Trichomonas vaginalis*, which causes a sexually transmitted disease in humans, is a parabasilid. The trypanosomes include *Trypanosoma brucei*, which causes African sleeping sickness. 26.4 • The main groups of chromalveolates are the alveolates (characterized by alveoli, flattened vesicles inside their plasma membranes) and stramenopiles (most of which have motile cells with two flagella, one of which bears tiny hairlike projections). • Like dinoflagellates, apicomplexans have alveoli. There is evidence that the chloroplasts of photosynthetic dinoflagellates were derived from a red alga through secondary endosymbiosis; the apicomplexans carry a nonphotosynthetic chloroplast remnant also thought to have originated from a red alga. • A water mold, *Phytophthora infestans*, causes light blight of potatoes and was responsible for the 19th-century Irish potato famine. • Diatoms are major producers in the ocean. Brown algae are also producers and provide habitat for many marine organisms. 26.5 • The term *rhizarian* (“root”) refers to the threadlike cytoplasmic projections extended by forams and actinopods. 26.6 • Red algae and green algae share similarities with land plants at the molecular level, and, like land plants, have chloroplasts surrounded by only two external membranes. 26.7 • The cytoplasmic projections of the amoebozoans are rounded and wide (i.e., lobose) as opposed to those of the rhizarians, which are thin and threadlike. • The choanoflagellates are the unikonts most structurally and genetically similar to animals.

Figure Questions

FIG. 26-2 Two. **FIG. 26-3** The common ancestor of the brown algae and the water molds is most likely a stramenopile that evolved before the water mold clade branched off. The likely common ancestor of animals and fungi would be an opisthokont that evolved before the fungal clade branched off. **FIG. 26-17** Unikont.

Test Your Understanding

12. Also compare your sketches to Figures 26-5b (*Euglena*) and 26-8b (*Paramecium*).

Euglena

Paramecium

13. The protists include many, but not all, of the descendants of the ancestral eukaryote at the base of the cladogram (i.e., land plants, fungi, and animals are not protists). 14. Actin (red) is found in the microvilli in the choanoflagellate collar, tubulin (green) in the flagellum and as part of the cytoskeleton, and DNA (blue) in the nucleus. 15. The available evidence supports the hypothesis that the chloroplast remnant in the cells of the malaria parasite *Plasmodium* evolved by serial endosymbiosis from a red algal chloroplast. Although nonphotosynthetic, it is essential to the parasite's survival and therefore a potential target for drug therapy. Unfortunately, the use of chemotherapies against malaria, and insecticides against the *Anopheles* mosquito, are selecting for the evolution of resistant strains of both the parasite and the vector.

Chapter 27

Checkpoint

27.1 • Challenges for terrestrial plants include preventing desiccation, obtaining CO₂ for photosynthesis without excessive water loss, providing a means for sperm and egg to meet, and protection of the embryo. • The presence of a waxy cuticle helps prevent desiccation of the plant body, and gas exchange is facilitated by stomata. Various mechanisms have evolved for sperm and egg to meet, and embryos are protected within a multicellular female gametangium. • Many lines of molecular evidence link the land plants more closely to the charophytes than to other groups of Archaeplastids.

•

Also compare your diagram to Figure 27-2. **27.2** • The haploid gametophyte generation in mosses includes the following: spores, protonema (each develops from a spore), archegonia

(produce egg cells by mitosis), and antheridia (produce sperm by mitosis). • Mosses, liverworts, and hornworts lack vascular tissue and share similar gametophyte dominant life cycles. They most obviously differ in their body forms: mosses (leafy gametophytes), liverworts (thalloid or leafy gametophytes), and hornworts (thalloid gametophytes that give rise to sporophytes that exhibit indeterminate growth). **27.3** • Unlike algae and bryophytes, ferns have dominant sporophytes that possess vascular tissue, as well as stems, leaves (megaphylls), and roots. • Microphylls are small, with a single vascular strand; megaphylls are typically larger and each possesses more than one vascular strand. • The diploid sporophyte generation of ferns includes the following: zygote, roots, rhizome, frond, sorus, and sporangium. • Whisk ferns and horsetails are classified with ferns based on characteristics such as similarities in DNA and sperm structure. • The heterosporous life cycle is characterized by the formation of two kinds of spores and hence two kinds of gametophytes: megaspores (give rise to female gametophytes) and microspores (give rise to male gametophytes).

Figure Questions

FIG. 27-2 Both diploid (sporophyte generation) and haploid (gametophyte generation) cells undergo mitosis in the plant life cycle. **FIG. 27-5** The cladogram indicates that all land plants have multicellular embryos (unlike their green algal most recent common ancestor).

FIG. 27-7

Also compare your sketch to Figure 27-7, step 3. The tissue of the archegonium belongs to the haploid gametophyte generation and the developing embryo belongs to the new sporophyte generation. **FIG. 27-11** You would not expect *Physcomitrella* to possess genes required to produce functional xylem and phloem because it lacks these tissues. However, evolution builds on pre-existing genetic variation, so it is possible that gene sequences that were important in the evolution of xylem and phloem may be found in the *Physcomitrella* genome. **FIG. 27-13** Ferns. **FIG. 27-16** The fern life cycle is sporophyte dominant, unlike the gametophyte dominant life cycle of mosses. **FIG. 27-19** The heterosporous life cycle, like the basic plant life cycle, consists of a multicellular haploid gametophyte generation and a multicellular diploid sporophyte generation.

Test Your Understanding

1. d 2. b 3. d 4. d 5. a 6. b 7. c 8. a 9. c 10. d 11. c 12. c

13.

Also compare your diagram to Figure 27-19. 14. (a) Plants that are dependent on water for fertilization are limited to aquatic environments or those in which sperm can be transported in a film of water. (b) Unlike homospory, heterospory can lead to a life cycle in which seeds can be formed. Seeds are advantageous for life on land because they provide both protection and nutrition for new sporophyte plants. 15. Non-vascular bryophytes. 16. Based on current evidence, you would probably place the rhyniophytes in the fern clade because they possessed xylem, although their relationship to other ferns remains unclear. Their line would not extend to the tips of the rest of the cladogram because they are all extinct, and it is not clear if any extant group descended directly from them.

Chapter 28

Checkpoint

28.1 • An ovule is a megasporangium surrounded by integuments. • Unlike the naked seeds of gymnosperms, those of angiosperms are surrounded by an ovary wall. **28.2** • The sporophyte is the dominant generation in the pine. Gymnosperms are commonly wind pollinated, although some, such as cycads, may be pollinated by insects. • Gymnosperms possess seeds, lack free-living gametophytes, and, unlike most seedless plants, are heterosporous. • The four groups of gymnosperms are the conifers, cycads, ginkgoes, and gnetophytes. • Unlike ginkgoes and gnetophytes, cycads produce seeds in cones. Both cycads and ginkgoes have flagellated motile sperm cells (unlike gnetophytes). Ginkgoes have unique fan-shaped leaves and produce exposed seeds; gnetophytes also produce exposed seeds, and unlike all other gymnosperms, have vessel elements in their xylem. **28.3** • The

vascular tissue of angiosperms has more efficient components than that of gymnosperms; it includes vessel elements in the xylem and sieve tube elements in the phloem. • The flowering plant life cycle is characterized by a unique double fertilization process, which provides endosperm for the nutrition of the new sporophyte. Angiosperm seeds are enclosed in a fruit, which protects the seeds and promotes their dispersal. • Monocots have embryos with one cotyledon; eudicot embryos have two cotyledons. Refer to Table 28-2 to compare additional distinguishing characteristics. • Fertilization in gymnosperms yields a diploid zygote; double fertilization in angiosperms yields a diploid zygote, plus a triploid cell that develops into the endosperm. **28.4** • Unlike the seed ferns, progymnosperms reproduced by spores (not seeds). • *Archaeofructus*, the oldest known fossil angiosperm, had carpels that enclosed ovules. • Based on molecular data, monocots are considered core angiosperms (a sister clade to the eudicots).

Figure Questions

FIG. 28-2 Gnetophytes. **FIG. 28-4** A pine pollen grain is a haploid immature microgametophyte (not a gamete), which will mature to produce sperm (male gametes) by mitosis. **FIG. 28-13** Microspores and megaspores are haploid cells that divide by mitosis to give rise to multicellular microgametophytes and megagametophytes, respectively. Megagametophytes produce eggs (female gametes) and microgametophytes produce sperm (male gametes) by mitosis. **FIG. 28-18** The basal angiosperm *Amborella* lacks vessel elements, which are present in water lilies and star anise. **FIG. 28-19** In gymnosperms, the haploid female gametophyte forms the nutritive tissue in the seed.

Test Your Understanding

1. e 2. b 3. d 4. a 5. e 6. d 7. b 8. d 9. a 10. c 11. a 12. c 13. Eudicot angiosperm: five petals, netted leaf venation.

14.

Also compare your sketch to Figures 28-4 and 28-13. Embryos (new sporophytes) and seed coats (parent sporophyte tissue) are diploid. The gymnosperm nutritive tissue is the haploid female gametophyte; that of the monocot is triploid endosperm. 15. Both seedless and seed plants have the same basic life cycle, with an alternation of multicellular haploid gametophyte and multicellular diploid sporophyte generations. Most

seedless plants are homosporous; all seed plants are heterosporous. 16. Bisexual flowers increase the odds that an individual will be able to reproduce sexually because the individual has the potential to become a male parent, a female parent, or both. 17. Algae, mosses, and ferns all require at least a thin film of water for sperm transport in sexual reproduction. Both gymnosperms and angiosperms enclose their gametes and embryos in structures that provide some measure of protection from desiccation, an important adaptation to life on land. 18. Given the information currently available in the fossil record, the progymnosperm clade would branch off from the cladogram after the ferns because they had gymnosperm-like vascular tissue; it would branch off before the evolution of seeds, which they lacked.

Chapter 29

Checkpoint

29.1 • Fungi are distinguished from other simple eukaryotes by nutrition by absorption from the environment and by cell walls of chitin. • Yeasts are unicellular; molds form filamentous mycelia composed of hyphae. **29.2** • A diploid cell contains two sets of chromosomes in a single nucleus. A dikaryotic cell contains two kinds of nuclei, each with a single set of chromosomes.

• See figure below; also compare your sketch to Figure 29-4.

29.3 • Chytrids, like other opisthokonts but unlike all other fungi, produce flagellate cells at some stage of their life cycle. • Zygomycetes: produce sexual zygospores. Glomeromycetes: sexual spores are large, multinucleate blastospores. Ascomycetes: asci produce sexual ascospores. Basidiomycetes: basidia produce sexual basidiospores.

• See figure below; also compare your diagrams to Figures 29-13 and 29-17.

• An ascocarp is a fruiting body that produces ascospores (sexual spores) in asci. A basidiocarp is a fruiting body that produces basidiospores (sexual spores) on basidia. **29.4** • Fungal decomposers recycle important nutrients back into the environment and are particularly important in breaking down certain materials such as cellulose and lignin. • Plants provide organic nutrients to mycorrhizal fungi, which in turn make soil nutrients available by decomposing organic matter; through their larger surface area, they increase the ability of plant roots to absorb water and minerals. • The photoautotroph is the likely host because it can typically grow well when separated from the fungal partner. The fungal partner does not grow well on its own, so it is the likely parasite. **29.5** • Studies of fungi such as *Saccharomyces*, *Aspergillus*, and *Neurospora* as model organisms have yielded important insights in biology and medicine. Some fungi produce valuable medications, while others are responsible for causing serious diseases. • Some fungi benefit plants by participating in mycorrhizal associations; by recycling nutrients in the environment, making them available to plants; by degrading toxins in the environment; and by controlling insects and other pests. Other fungi cause serious plant diseases.

Figure Questions

FIG. 29-4 Beadle and Tatum irradiated asexual spores of *Neurospora* to induce mutations, and then selected the mutant strains with differing nutritional requirements. **FIG. 29-7** Animals produce gametes by meiosis. **FIG. 29-9** Haploid gametangia function as gametes in the zygomycete life cycle. **FIG. 29-13** Conidia and ascospores are haploid; the ascocarp is dikaryotic; and the zygote is diploid. **FIG. 29-17** The basidiospore and primary mycelium are haploid; secondary mycelium and basidiocarp are dikaryotic; and the zygote is diploid. **FIG. 29-19** The potential loss of mycorrhizal fungi (negatively affected by acid precipitation) will reduce the ability of their plant partners to obtain water and essential mineral nutrients. The problem can be alleviated by controls on industries responsible for releasing acid-causing pollutants into the atmosphere.

Test Your Understanding

1. a 2. b 3. e 4. d 5. d 6. a 7. e 8. c 9. c 10. c 11. b 12. e 13. (a) Dikaryotic. (b) Dikaryotic, preparing for sexual reproduction.

Also compare your sketches to steps 4 and 5 of Figure 29-17. 14. Fungal mycelia form an extensive, but not easily seen, network of microscopic hyphae in the soil. 15. (a) Fungi are classified as opisthokonts based on molecular data and the presence of platelike cristae in their mitochondria. The flagella of chytrids (the only fungi that have a life cycle that includes flagellate cells) are single and posterior, as in flagellate opisthokonts. (b) Microsporidia are classified as fungi based on gene sequences. (c) Ascomycetes and basidiomycetes are sister clades, thought to have diverged after the evolution of the dikaryotic stage in the life cycle. 16. Fungi, like humans, are eukaryotes. Consequently, there are fewer differences between humans and fungi that can be exploited in the development of safe and effective treatment options for fungal diseases. 17. *Pro*: The genomes of the fungi that are model organisms provide important insights into the genetic basis of a vast array of processes in other organisms, including humans. Knowledge of the genomes of economically important fungi (both beneficial and harmful) can be exploited in making these fungi more useful or to provide ways to combat them. *Con*: The scientific resources required can be costly and expenditures must be balanced with other important societal and scientific goals (but keep in mind that the latest advances in genome sequencing technology and bioinformatics are reducing, not increasing, costs).

Chapter 30

Checkpoint

30.1 • Like other animals, sponges are multicellular, eukaryotic heterotrophs; they have an extracellular matrix containing collagen; sponges exchange gases, circulate materials, and dispose of waste; they are capable of locomotion and can reproduce sexually. **30.2** • Advantages of the marine environment for animals are the buoyancy of sea water, which provides sup-

port; the large volume of the ocean, which keeps the water temperature relatively stable; and the similar osmotic concentration of animal body fluids and sea water, which helps maintain fluid and salt homeostasis. • Animal adaptations to the terrestrial environment are a body covering that minimizes desiccation, internal respiratory organs that reduce fluid loss; internal fertilization; protective egg, shell, or internal embryo development; skeletal and muscular support; and behavioral and physiological adaptations for maintaining body temperature. **30.3** • The Cambrian radiation was the rapid appearance of a great variety of body plans evidenced by fossils dating to the Early and Middle Cambrian time periods. • According to the current hypothesis, most major groups of animals evolved several hundred million years before they appeared in the fossil record, suggesting that the Cambrian radiation was a rapid evolution of new animal body plans among clades that already existed. • The discovery of *Hox* genes helped biologists understand that similarities in molecular development among different animal groups suggest that they had a common ancestor because all the *Hox* gene groups had evolved by the beginning of the Cambrian period. Further study has shown that regulation by *Hox* gene groups has been linked with the development of wings or legs. **30.4** • Animals are classified based on radial symmetry, in which the animal can be divided into two mirror images by multiple planes through the central axis, or bilateral symmetry, in which an animal can be divided into two mirror images by only one plane through the central axis. • Some differences between protostomes and deuterostomes are in the patterns of cleavage. For example, in early development, early cell division consists of spiral cleavage in protostomes and radial cleavage in deuterostomes. Also, the early four-cell embryo of protostomes exhibits a pattern of determinate cleavage, while the first embryonic cells of deuterostomes undergo indeterminate cleavage. Further, in protostomes the blastula develops into a mouth, while in the deuterostomes the blastula develops into an anus, and the mouth, a second opening, forms later.

Refer also to Figure 30-6 for a cladogram illustrating the evolutionary relationships among and major differences between the three main clades of bilateral animals.

Figure Question

FIG. 30-6 Nematodes, tardigrades, onychophorans, and arthropods are the animal groups assigned to the Ecdysozoa. The shared derived character present in the Ecdysozoa clade is molting.

A-50 / Appendix E

11. You could decide that the organism is an animal if the following criteria are observed: multicellular, eukaryotic, heterotrophic, extracellular matrix contains collagen, locomotion, and sexual reproduction. 12. Large molecular data sets, physical and molecular examination of fossils and existent animals, morphology, and patterns of development were some of the types of data that biologists used to determine these phylogenetic relationships. 13. An example of a hypothesis regarding segmentation that can be logically defended: The cladogram in Figure 30-6a shows that segmentation is not present in all groups in any of the clades with segmented animals. 14. The branch would occur just below the node where Lophotrochozoa and Ecdysozoa branch, just above the place labeled “proto-stome pattern of development.”

Chapter 31

Checkpoint

31.1 • Choanocytes resemble choanoflagellates (protists) in form and function. Many systematists think that sponges and other animals share a common ancestor with choanoflagellates. Choanocytes create water current in the sponge, bringing food and oxygen in and carrying out carbon dioxide and wastes. Choanocytes also phagocytize food particles. • Cnidarians are more highly organized than sponges; they have two-tissue cell layers, a nerve net with simple sense organs, a hydrostatic skeleton for body support and movement, and cnidocytes, with stinging organelles for defense and predation.

See also Fig. 31-5. • Ctenophores are like cnidarians in that both have a similar body plan, two cell layers, and a nerve net. Ctenophores are different from cnidarians because they lack stinging nematocysts; their digestive system has a mouth for intake and anal pores for waste removal, while cnidarians have only one opening. 31.2 • Cephalization is an advantage because forward-moving organisms with a concentration of sense organs in a head area are better able to search for food, shelter, and mates, and can be alerted to predators and dangerous conditions. Advantages of having a coelom include room for more complex organ systems with organs attached to the body wall and space for gonads to develop. • Nematodes are classified as lophotrochozoans because they have a rhynchocoel, which is a remnant of a coelomate ancestor; recent molecular evidence and cladistic analysis place them in the lophotrochozoan clade. • Gastropods have a large, flat foot for locomotion, a mantle that functions as a lung (for land snails), and torsion, which protects the head. They have a slow-moving lifestyle and retreat to their shell when threatened. Cephalopods have very complex eyes; a body containing a siphon, enabling rapid swimming for predation and evasion; and defense mechanisms such as chromatophores and an ink sac. They live a fast-moving predator lifestyle, and many exhibit highly adaptable vertebrate-like behavior. • Flatworms have a simple nervous system and are acoelomate. Mollusks have a muscular foot and a mantle. Annelids have segmented bodies in which each segment has

its own muscles, segmented organs, and most members have setae (with the exception of leeches). 31.3 • Nematodes differ from flatworms because they molt, have a thick cuticle, and a pseudocoelom. • Arthropod characteristics for success are segmentation for specialized body functions; an exoskeleton to provide protection from predators and desiccation; paired, jointed appendages, which are modified for diverse functions; and a more developed nervous system, which may include hearing organs, antennae, and compound eyes. • Crustaceans have three body divisions, while chelicerates have two; crustaceans have biramous appendages, while chelicerates are uniramous; crustaceans have antennae, while chelicerates do not; and crustaceans develop through larval stages, while most chelicerates exhibit direct development. • Adaptations that have made insects very successful include the specialized insect body plan, ability of many insects to fly, great reproductive capacity, and offensive and defensive adaptations (cryptic coloration, toxins, pheromones).

Figure Question

FIG. 31-32 All four stages are diploid; the adult produces haploid gametes.

Test Your Understanding

1. a 2. c 3. b 4. d 5. a 6. e 7. b 8. d 9. b 10. e 11. d

12.

See also Fig. 31-4. 13. Having a coelom resulted in advantages such as highly developed, complex organ systems. Many internal organs are suspended from folds of tissue lining the coelom; these organs, for example, the digestive tube, can move independently of the outer body wall. In some animals, fluid in the coelom helps transport food, oxygen, and wastes; cells bathed by the coelomic fluid can exchange materials such as food, oxygen, and wastes with it. The coelom also provides space for production and storage of gametes. 14. (a) Cephalization is an advantage because centralized sense organs efficiently promoted greater nervous and sensory adaptations (offensive and defensive), but it can be a disadvantage to have the majority of sensory organs in the head, which could be easily harmed and destroyed. (b) The arthropod exoskeleton was an evolutionary advantage that provided strong armor and muscle support but was a disadvantage when the animal molted, leaving it vulnerable while waiting for its new exoskeleton to harden. (c) Specialized segmentation was advantageous in the development of legs and wings for locomotion but was a disadvantage if that area became damaged where other segments could no longer substitute for the function. 15. The animal would be classified in the lophotrochozoan clade due to a segmented body, bristles, and no observable head. Based on Figure 30-6a, the animal would likely be classified as an annelid, between the unsegmented mollusks and lophophorates, which do have an obvious mouth end. 16. Biologists have recently recognized that animals with very similar body cavities may have great evolutionary and genetic differences based on molecular phylogenetic analyses. 17. Some animals, such as parasites, became adapted to environments in which they no longer used some of their organs, or even organ systems. For example, the tapeworm lives inside the digestive system of its host and absorbs food through its body wall. Through the course of evolution these structures were not selected for, eventually resulting in their loss. Tapeworms no longer have a mouth or digestive system. 18. Insects that undergo complete metamorphosis may be more successful than other insects because the larval form and the adult form are very different and occupy different habitats. They do not compete with each other for food and other resources. 19. Coral reefs are one of the most productive ecosystems; they provide habitats for thousands of different species. Coral reef health is an indicator

of the quality and temperature of our oceans. We humans are dependent on healthy, pollution-free oceans, as are all living organisms on this planet we share. Damage to coral reefs from human-caused water temperature increase, higher acidity from carbon dioxide release, reduced water clarity from contaminants, introduction of toxic pollutants, and physical destruction of reefs are all problems society must address in partnership with scientists to develop successful technologies for remediation.

Chapter 32

Checkpoint

32.1 • Three shared derived characteristics of deuterostomes are radial cleavage, indeterminate cleavage in which the blastopore develops into the anus and the mouth develops from the second opening of the embryo, and pharyngeal slits. **32.2** • Three derived characters of echinoderms are adult pentaradial symmetry, allowing them to respond to all directions of their environment; a water vascular system for feeding, gas exchange, and hydrostatic support for locomotion; and a calcium carbonate endoskeleton covered by a ciliated epidermis with spines, which protects them from predation. • Sea stars are different from crinoids because their mouths are on the underside of the disc, not the upper side. Most sea stars are active predators and scavengers, while crinoids move very little or are sessile and obtain food by removing microorganisms in suspension. Sea stars are different from sea urchins because they have movable arms, while sea urchins have flattened, fused plates and no arms but do have movable, long, sharp spines that aid locomotion and provide protection. **32.3** • Four shared derived characters of chordates are a notochord; the dorsal, tubular nerve cord; the postanal tail; and an endostyle or thyroid gland. • The chordate nerve chord differs from most other animals because it is dorsal, hollow, and single rather than ventral, solid, and double. • Human jaws are related to early chordate pharyngeal slits because the anterior pharyngeal arches of the slits evolved into jaws during early vertebrate evolution. **32.4** • A tunicate larva has the four chordate characters—notochord; dorsal, tubular nerve chord; postanal tail; and endostyle, while a tunicate adult loses the notochord, postanal tail, and most of the nervous system. • If the organism lacks paired fins, eyes, and jaws, it would be identified as a lancelet instead of a fish. **32.5** • The four shared derived characters of vertebrates are the vertebral column, the cranium, neural crest cells, and pronounced cephalization with 10 to 12 pairs of cranial nerves and developed sensory organs. • The main clades (classes) of fishes are Myxini, Petromyzontida, Chondrichthyes, Actinopterygii, Actinistia, and Dipnoi. The main groups of tetrapods are amphibians, mammals, and reptiles. **32.6** • Like ostracoderms, lampreys and hagfishes do not have paired fins or jaws.

32.7 • Placoderms were the first fish to have jaws and paired fins, characteristics that were passed on to modern fishes. Lungfishes retained lungs from their sarcopterygian ancestors and evolved fleshy fins from which limbs of tetrapods developed. Ray-finned fishes underwent adaptive radiation, aided by additional clusters of *Hox* genes, which increased the amount of genetic material for evolution and promoted the diversification of modern bony fishes. *Tiktaalik* was a fish that had limb-like fins and tetrapod characteristics (movable neck and ribs that supported lungs); it was a transitional form between fishes and tetrapods. • Amphibians undergo metamorphosis in which they lose their gills, gill slits, and tail, and grow limbs. Simple lungs and moist skin allow for respiration/gas exchange on land. Mucus-producing glands develop to help maintain skin moisture and make the animal slippery to evade land predators. Many adult amphibians also have glands that secrete poison for protection. **32.8** • Adaptations that allow amniotes to be terrestrial are the amniotic egg, internal fertilization, a body covering that retards water loss, and physiological mechanisms to retain water. • Birds and mammals are endotherms. Advantages of endothermy are high metabolic rate allowing for a high level of activity and decreased vulnerability to temperature fluctuations. • Birds and reptiles are now correctly classified as a single clade based on fossil records and molecular analyses; they evolved from feathered, saurischian dinosaurs, bipedal theropods, which share characteristics such as feet with three digits, thin-walled, hollow bones, and a wishbone. Also, modern birds retain reptilian scales on their feet and legs. • The main clades are (1) the protherian mammals, the monotremes that lay eggs and secrete milk for their young (do not have nipples), and (2) the therian clade, which includes the metatheria, the marsupials that give birth to undeveloped young, which move to a pouch on the mother to continue development. They obtain milk from a nipple in the pouch. The therian clade also includes the eutherian mammals, which have a well-developed placenta; the young are born more developed and obtain milk from nipples on the mother's chest or abdomen.

Figure Questions

FIG. 32-4 The vertebrate nerve cord differentiates into the brain and spinal cord. **FIG. 32-7** The pronounced cephalization that was part of the evolution of vertebrates from jawless fish to tetrapods allowed for a larger, more complex brain. As the brain and sensory organs further evolved, various regulatory and cognitive systems could become more complex; increased brain complexity resulted in greater success in competing with other animals for food and mates. **FIG. 32-20** Birds are more closely related to the extinct branches of reptiles because they share the same archosaur ancestor. Mammals share a distant relationship with all members of the diapsids through the ancestor with the amniotic egg at the root of the cladogram.

Test Your Understanding

1. b 2. a 3. d 4. e 5. e 6. c 7. c

8.

See also Fig. 32-25. 9. Sea urchins are not cnidarians because they have the characteristics of deuterostomes and echinoderms. Radial symmetry may have evolved as an adaptation to the sessile lifestyle of early echinoderms. 10. Birds share the same archosaur ancestor based on fossil records and molecular analyses; they are most closely related to saurischian dinosaurs (now extinct) and share characteristics of the dinosaurs such as bipedal locomotion, feet with three digits, thin-walled, hollow bones, a wishbone, and scales on their legs. 11. Echinoderms and chordates are both members of the deuterostomes and share derived characters at some stage of life such as radial cleavage, indeterminate cleavage in which the blastopore develops into the anus and the mouth develops from the second opening of the embryo, and pharyngeal slits. 12. The dorsal, tubular nerve cord would identify the animal as a chordate. The cranium would place the animal in vertebrates. Skin with scales and two atria/two ventricles would indicate the animal is closely related to a crocodilian, bird, or saurischian dinosaur. The animal discovery would be placed somewhere between crocodilians and birds on the cladogram. 13. Sea turtles can be protected by scientists sharing research about the animals and their needs with the public; educators can inform society about sea turtle conservation and lead activities to improve habitat, reduce poaching, and pass conservation laws; and technology can be developed to support more complex research, rehabilitate habitat, control poaching, and improve health care for turtles.

Chapter 33

Checkpoint

33.1 • Roots absorb water and minerals; shoots bear the leaves, which absorb CO_2 and serve as the main organs of photosynthesis. • The ground tissue system carries out photosynthesis,

and provides for storage and support. The *vascular tissue system* conducts water, minerals, and carbohydrates. The *dermal tissue system* provides a covering for the plant body. • Parenchyma tissue contains thin-walled parenchyma cells that carry out such functions as photosynthesis, storage, and secretion. Collenchyma tissue consists of collenchyma cells, which provide flexible support by means of their thickened primary cell walls. The sclerenchyma cells (sclerids and fibers) in sclerenchyma tissue have thickened secondary cell walls that provide strong support. • Xylem is the tissue responsible for conduction of water and minerals by means of tracheids (with pits) and vessel elements (with perforations in end walls as well as pits). Sieve tube elements in phloem are responsible for conducting dissolved sugar, which has been moved into them by companion cells. • The epidermis, the outer covering of the plant body, functions in protection and also includes guard cells in leaves that regulate stomata as well as trichomes, which carry out varied functions. The underlying periderm, like the epidermis, has protective functions. It also contains meristematic and storage cells. **33.2** • Plant meristems provide new cells for growth. Animal growth does not involve meristems. • Secondary growth is an increase in girth; primary growth is an increase in length. • Apical meristems are responsible for primary growth; lateral meristems provide for secondary growth. **33.3** • Cell expansion typically precedes cell differentiation. • Changes in gene activity (differential gene expression) are responsible for pattern formation. • Cells alter the expression of their genes in response to positional information received from their environment. These changes bring about pattern formation, which eventually leads to morphogenesis. • Many developmental mutants of *Arabidopsis*, a small plant with a fast life cycle, are available for study. Information gained from these investigations can then be applied to research on other plants.

Figure Questions

FIG. 33-1 Air: CO₂; soil: water. **FIG. 33-2** For transport to take place, the vascular tissue must be continuous throughout the plant. The plant would die because there would be no transport between the leaves and the roots.

12.

A-54 / Appendix E

13.

Also compare your sketch to Figure 33-11.

14.

Also compare your sketch to Figure 33-12. Note that your arrow should be perpendicular to the cellulose microfibrils. 15. The initials will still be 4 ft above the ground. The increase in the height of the tree occurred at multiple apical meristems. 16. Unlike dead cells (sclerenchyma), living cells (bone) require maintenance in the form of nutrition, gas exchange, and waste removal. On the other hand, dead cells cannot be repaired or replaced. 17. Vessel elements are more efficient water conductors than are tracheids. It is thought that possession of both tracheids and vessel elements has contributed to the adaptive radiation of angiosperms into a wide variety of environments. 18. The relationship of the genome to various plant functions can be studied more easily in *Arabidopsis* than in most other plants. The pace of research is enhanced when these insights are applied to investigations on commercially important plants.

Chapter 34

Checkpoint

34.1 • Leaves are covered with a waxy cuticle and may also have trichomes that are specialized to reduce water loss. Gas exchange is limited to stomata, tiny pores whose opening and closing can be controlled. • Mesophyll, the leaf's photosynthetic ground tissue, typically consists of palisade mesophyll under the upper epidermis, and spongy mesophyll below. • A vascular bundle contains xylem (upper) and phloem (below). • Leaf mesophyll cells receive water and dissolved minerals from the xylem; the carbohydrate products of photosynthesis are transported away by the phloem. CO₂ enters the leaf through stomata, which also provide for the exit of excess O₂ (i.e., that not used for respiration by leaf cells). **34.2** • Blue light begins the

process of stomatal opening by causing the activation of proton pumps in the plasma membranes of guard cells. It also triggers synthesis of malic acid and hydrolysis of starch. • In stomatal opening, proton pumps (activated by blue light) actively transport H^+ out of the guard cells. This resulting electrochemical gradient is responsible for the opening of voltage-activated ion channels through which K^+ and Cl^- enter the guard cells by facilitated diffusion; water then enters by osmosis. The resulting turgor pressure in the guard cells causes them to change shape, resulting in stomatal opening. The stomata are maintained in an open position during the day due to maintenance of osmotic pressure by sucrose produced by photosynthesis. When sucrose concentration declines at the end of the day, the guard cells lose turgor as they lose water by osmosis and the stomata close. **34.3** • The leaf cuticle and stomata limit water loss by transpiration. • Sunlight, higher temperatures, lower relative humidity, and higher wind speeds all increase the rate of transpiration. • Transpiration benefits plants by making water and minerals available throughout the plant. It is harmful when it results in excess water loss. • In guttation, liquid water is forced out of vein endings in the leaves of small plants as a result of water entering the roots when soil moisture is high and transpiration is negligible. Transpiration is the evaporation of water from aerial parts of the plant. **34.4** • Loss of leaves in autumn is a mechanism to reduce water loss during winter when cold temperatures (and perhaps freezing) make water less available from the soil. • Leaf abscission occurs after enzymes have dissolved the middle lamella between the cells in the abscission zone. • The abscission zone is an area where a leaf petiole attaches to a stem. It is composed mainly of thin-walled parenchyma cells. It also includes cork cells, which will remain with the stem as a protective layer after the leaf has abscised. **34.5** • Spines: protection from herbivores; tendrils: aid in climbing; bud scales: protection of meristematic tissue. • Bulbs: storage of food; succulent leaves: storage of water. • Certain leaves of carnivorous plants are specialized to capture and digest small animals such as insects.

Figure Questions

FIG. 34-3 Control of developmental processes is not limited to genes that code for transcription factors. Other examples include genes that code for components of signaling pathways, regulatory RNAs, and a great many more. **FIG. 34-10** During photosynthesis during the day, guard cells produce sucrose, which is osmotically active and helps maintain their turgor pressure, keeping the stomata open.

Test Your Understanding

1. c 2. d 3. d 4. e 5. d 6. a 7. e 8. c 9. a 10. c 11. a 12. You would expect a higher concentration of guard cells in the lower epidermis. 13. In the stem, an arrangement with the xylem toward the center and the phloem toward the periphery would account

for the leaf arrangement (xylem toward the upper epidermis and the phloem toward the lower epidermis).

Also compare your simple drawing to Figure 34-4. Mesophyll cells and guard cells should contain chloroplasts. 15. A few large leaves present a large area for photosynthesis, but may effectively shade leaves below them and also present a large area for potential water loss. This might not be a great disadvantage in a humid climate. Many small leaves may have less area for photosynthesis, but they will shade each other less. Collectively they can be oriented in many directions to capture light and may lose much less water. 16. Leaf abscission helps prevent water loss during the winter when photosynthesis is negligible and less water is available from the soil. The smaller surface area, thick cuticle, and sunken stomata of conifer leaves (needles) are adaptations that allow conifers to survive winter without leaf abscission. 17. Agricultural plant yields depend on photosynthesis, which in turn depends on availability of CO_2 (through open stomata). Water loss (also through open stomata) reduces plant yields.

Chapter 35

Checkpoint

35.1 • In a stem cross section, the vascular tissue of a primary eudicot stem is arranged in a circle; vascular bundles of a monocot stem are scattered. • Vascular cambium gives rise to secondary xylem (to the inside) and secondary phloem (to the outside). Cork cambium produces periderm (outer bark). • When secondary growth occurs, the primary tissues become non-functional (e.g., primary xylem) or become destroyed (e.g., primary phloem). • Growth rings are a consequence of the differences between springwood (with large-diameter tracheids

and vessel elements formed when water is plentiful) and summerwood (with smaller water-conducting cells, formed when water is less available). • Terminal buds form at the tips of stems; axillary buds form in the axils of plant leaves. **35.2** • Water moves from a region of higher water potential (generally less negative) to a region of lower water potential (generally more negative). • It has been demonstrated that tension–cohesion is strong enough to pull water as high as 130 m. The tallest known tree is 115.7 m high. **35.3** • Xylem transport occurs upward from roots to leaves. Phloem transport is from a source to a sink (upward or downward). • In the pressure–flow model, companion cells load sugar into sieve tube elements at the source and water follows by osmosis. This increases the hydrostatic pressure inside the sieve tube, pushing the contents toward the sink. The hydrostatic pressure is lower at the sink because companion cells unload sugar from the sieve tube elements, causing water to leave by osmosis.

Figure Questions

FIG. 35-3 The irregularly arranged (scattered) vascular bundles of a monocot stem would not provide for regular positioning of a vascular cambium within the stem. **FIG. 35-7** The branch is two years old (two sets of bud scale scars). There are two twigs with terminal buds at the end. **FIG. 35-11** Water would not be able to move from the soil to the root (and might even move out of the root) if the water potential of the soil were more negative than that of the root. **FIG. 35-12** The direction of translocation is from a source (in this case a root where starch is broken down) to a sink (in this case a developing leaf cell). Therefore the direction of transport would be upward in the stem. **FIG. 35-13** Outward movement of fluid would not occur because, unlike phloem, the xylem of a large plant is not under positive pressure.

Test Your Understanding

1. d 2. e 3. b 4. b 5. a 6. b 7. e 8. c 9. b 10. a 11. b

12. Also compare your drawing to Figure 35-4. The daughter cell formed to the outside of the meristematic cell should be labeled secondary phloem.

13. Periderm or outer bark (which is usually most easily peeled away) consists of remnants of primary phloem, cortex, and epidermis. 14. A tree 150 m tall would exceed the calculated maximum height for xylem transport by tension–cohesion (130 m). 15. One hypothesis would be that tropical vines must be strong and long lived to obtain adequate sunlight by growing to the

tops of tall rainforest trees. 16. Water will flow from the cell with higher (less negative) water potential (i.e., -1.5 MPa) to the cell with lower (more negative) water potential (i.e., -1.8 MPa).

Chapter 36

Checkpoint

36.1 • A fibrous root system is adapted to obtain water from a larger area of the soil surface; a taproot system has access to water deep underground. • A primary eudicot root has a central stele containing xylem and phloem. The center of the stele of a typical monocot root is occupied by pith surrounded by xylem and phloem arranged in alternating bundles. • Water and dissolved minerals move through the apoplast by way of interconnected cell walls. Water and minerals must cross at least one plasma membrane to enter the symplast, and then move from cell to cell through plasmodesmata. • The Casparian strip prevents materials from entering the center of the root without passing through the plasma membrane of an endodermal cell. • As in the stem, the root vascular cambium produces secondary xylem toward the inside and secondary phloem toward the outside. Cork cambium also contributes to the increase in girth as it produces cork cells and cork parenchyma cells. • Prop roots provide support; buttress roots provide support and help distribute shallow roots around a tree; and pneumatophores may assist in gas exchange by submerged roots. **36.2** • Mycorrhizae and root nodules are symbiotic associations that benefit plants. Mycorrhizal fungi aid plant roots in water and mineral uptake, and rhizobial bacteria fix nitrogen in root nodules. **36.3** • Minerals supply essential inorganic nutrients; organic matter provides many nutrients and holds water; air supplies oxygen for aerobic respiration and nitrogen that can be used by nitrogen-fixing bacteria; and soil water makes water available to plants and dissolves nutrients and gases. • In cation exchange, H^+ pumped into the soil by plant roots releases various mineral cations from negatively charged clay particles, making them available for absorption. • In weathering processes, rock is broken down by acids produced by organisms (particularly carbonic acid formed from carbon dioxide) and by alternating cycles of freezing and thawing. • Macronutrients are required in relatively large quantities (greater than 0.05% dry weight), whereas trace amounts of micronutrients are required. • Human mismanagement can damage soil through mineral depletion, soil erosion, and salt accumulation.

Figure Questions

FIG. 36-4 Many kinds of minerals are carried along dissolved in the water traveling through the nonselective apoplast. To enter the symplast, all minerals must pass through at least one plasma membrane. The plasma membranes therefore

act as “gatekeepers” that promote entry of minerals the plant requires, and typically exclude others. **FIG. 36-5** Water enters the endodermal cells by osmosis, which does not require a direct expenditure of energy. Energy is supplied indirectly by the energy-requiring transport of minerals, which creates relatively hypertonic conditions (i.e., lowers the effective water concentration) inside the endodermal cells. **FIG. 36-9** Stem vascular cambium, like root vascular cambium, produces secondary xylem inward and secondary phloem outward.

11.

Also compare your sketch to Figure 36-9. 12. The roots of woody plants, like their stems, produce annual rings. You should take a core sample of the root (as you would for a tree trunk) close to the entrance of the mineshaft and count the rings. 13. Without a microscope, look for the presence of root hairs. With a microscope, examine the internal structure in cross section and determine if a stele (characteristic of roots) is present. 14. In roots with secondary growth, all absorption occurs close to the tips, where only primary growth occurs and where the root hairs are found. 15. A shallow root system enables a cactus to capture more water from the infrequent rains that occur in the desert before the water runs off. 16. Understanding the development of root hairs could lead to ways of modifying agricultural crops to improve water and mineral absorption. Mycorrhizal associations benefit many

plants, and it is possible these benefits could be extended to additional types of agricultural crops. 17. The roots of the common reeds (*Phragmites australis*) absorbed almost all of the selenium. The plants should be uprooted and disposed of in a way that does not release selenium into the environment.

Chapter 37

Checkpoint

37.1 • Sepals, the outermost flower whorl, are typically more leaflike than the petals, which form the second whorl and are typically colored to attract pollinators. • Stamens and carpels are modified for reproduction. Stamens produce pollen and carpels produce ovules. • The female gametophyte of a flowering plant, produced within an ovule, is an embryo sac containing a haploid egg (which is fertilized to become the zygote) and two haploid polar nuclei (which are fertilized to become the triploid endosperm). • The immature male gametophytes of flowering plants are pollen grains, produced in anthers. **37.2** • Bee. • Wind. • Nectar or pollen are important rewards for many pollinators. Flowers have evolved to have colors that are visible to particular pollinators. Specific plant odors attract specific pollinators. **37.3** • Pollination is delivery of pollen to a flower stigma. Fertilization occurs when a pollen tube delivers sperm to fuse with the egg (producing an embryo) and with the two polar nuclei (producing the endosperm). • A eudicot embryo proceeds through the following stages: proembryo, globular stage embryo, heart stage embryo, torpedo stage embryo, and maturing embryo with two cotyledons. • A fruit is a mature ripened ovary. • Simple fruit develops from a single ovary with a single carpel or several fused carpels; aggregate fruit develops from a flower that contains several unfused carpels; multiple fruit develops from ovaries of many flowers; and accessory fruit develops from other tissues in addition to the ovary. • Animal-dispersed fruits and seeds tend to be edible, or they have barbs or other structures that attach them to the bodies of animals. **37.4** • All plant seeds require water for germination; the young plant would not be able to grow in the absence of water. Many seeds require a period of low temperature before they germinate; this prevents them from germinating in the fall and being unable to survive the winter. Some very small seeds require light for germination, ensuring that they will germinate near the soil surface. • The stem of a eudicot seedling protects its delicate tip by forming a hook as it emerges from the soil. The stem tip of a monocot seedling is enclosed by a protective coleoptile. **37.5** • Rhizomes are horizontal underground stems that produce new aerial shoots. Tubers are storage organs that develop from rhizomes and have axillary buds that can develop into new plants. • A bulb is composed mainly of fleshy leaves attached to short underground stem. The underground stem of a corm is enlarged relative to the papery leaves. • Apomixis is

the production of seeds enclosed in fruits without sexual reproduction. It has the advantages of the protections and dispersal methods usually provided by seeds and fruits. **37.6** • As in all organisms, asexual reproduction in plants results in offspring that are like their parents. Conversely, sexual reproduction results in genetically varied offspring. • Genetic variety in the offspring is considered adaptive because it typically results in at least some offspring that are better suited for survival and subsequent reproduction than their parents. However, it is costly because it also results in some less well-adapted offspring.

Figure Questions

FIG. 37-3 Haploid: megaspore, microspore, egg, polar nucleus, generative cell, sperm cell. Diploid: megasporocyte, microsporocyte. **FIG. 37-5** Some additional traits that might affect pollination in monkeyflowers would be scent (important to bumblebees but less so to hummingbirds) and rewards (nectar important to both, pollen more important to bumblebees).

Test Your Understanding

12. See figure below; also compare your sketch with Figure 37-1.

13. See figure below; also compare your sketches with Figures 37-1, 37-11, and 37-12.

14. The offspring of asexual reproduction might be expected to develop close to the parent plant because they are well suited to the same environmental conditions. You could test this hypothesis by growing the offspring in various locations, including close to the parent. Do you think there could be competition between the parent and offspring? 15. (a) Likely asexual. (b) Likely sexual. (c) Asexual (because all the offspring would be adapted to the parent's climate range) or could be sexual (because some of the offspring might be able to live in a somewhat different climate). 16. Plants produce seeds with elaiosomes to attract ants, which have coevolved to bury the seeds as they make use of the food reward. 17. Because almost all agricultural plants are flowering plants, an improved understanding of the control of their flowering can yield important benefits in agriculture. Similarly, almost every new crop begins with the sowing of seeds, so an understanding of their germination processes can be equally valuable.

Chapter 38

Checkpoint

38.1 • Phototropins absorb wavelengths other than yellow (which they reflect); they respond to blue light, which is one of the wavelengths they absorb. • Phototropism: directional growth in response to the direction of light; gravitropism: directional growth in response to gravity (either positive or negative); and thigmotropism: growth response to a mechanical stimulus. **38.2** • The signal provided by auxin activates a pathway that results in cell walls of target cells becoming acidified. These acidified cell walls are more plastic, enabling them to expand due to the force of the cell's turgor pressure. This cell expansion is a form of growth without cell division. • Auxin is transported from cell to cell in a plant in a unidirectional manner (polar transport). In phototropism, auxin is transported from the lighted side of the stem to the shaded side. Expansion of the cells on the shaded side causes the stem to bend toward the light. • (1) Seed germination: gibberellins, cytokinins, ethylene, brassinosteroids; (2) stem elongation: auxins, gibberellins; (3) fruit ripening: ethylene; (4) leaf abscission: ethylene; (5) seed dormancy: abscisic acid. **38.3** • Phytochrome is the main photoreceptor for photoperiodism and for shade avoidance. • One or more signal transduction pathways are activated when phytochrome undergoes changes in shape in response to light. Some of these pathways activate specific transcription factors that control gene expression. • Cryptochrome plays a role in resetting the biological clock responsible for maintaining circadian rhythms. **38.4** • The production of necrotic lesions is associated with the hypersensitive response. These areas of dead tissue limit or slow the spread of an infection.

Figure Questions

FIG. 38-5 One possible experiment would be to expose the uncovered coleoptiles to directional light for varying times, then cover their tips, and record bending responses. **FIG. 38-6** Coleoptile tips previously exposed to light could be placed on agar blocks, which would then be exposed to heat at varying temperatures and for varying durations of time. The agar blocks could then be placed on decapitated coleoptiles and the bending responses recorded.

Test Your Understanding

1. c 2. a 3. b 4. c 5. e 6. e 7. d 8. b 9. e 10. b 11. 1 → 4 → 3 → 5 → 2 12. (a) Plant will not flower; night length does not exceed 14 hours. (b) Plant will flower; night length exceeds 14 hours. (c) Plant will not flower; night length does not exceed *uninterrupted* 14 hours. 13. The plant will not flower at the equator (night length does not exceed 14 hours). 14. Negatively geotropic shoots grow up, into the air where CO₂ and light are available to support photosynthesis; positive gravitropic roots grow into the soil where they can absorb water and minerals. 15. A plant with a phytochrome gene mutation that affects flowering time would be at an evolutionary disadvantage for many reasons. For example, it might flower at a time when pollen or pollinators are not available. Its seeds might not have time to mature during the growing season or might mature too early and germinate during an unfavorable season. 16. Flowering is 100% when the day length is 10 hours and the night length is 14 hours; flowering is 0% when the day length is 16 hours and the night length is 8 hours. According to the graph, the critical night length for this plant is about 11 hours. 17. There is a growing body of evidence that plant-signaling molecules are involved in a wide range of processes affecting plant growth and development, all of which are of significant agricultural importance.

Chapter 39

Checkpoint

39.1 • Epithelial tissue forms a continuous sheet of cells covering a body surface or lining a body cavity. Its functions are to protect, absorb, secrete, and sense. Connective tissue consists of a few scattered cells separated by an intercellular substance, composed of fibers scattered throughout a matrix. Connective tissue joins other tissues of the body, supports the body and its organs, and protects underlying organs. • The air sacs of the lungs are lined with simple squamous epithelium. The cells are flat and arranged in a single layer to permit diffusion and passage of materials where little protection is required. • Skeletal muscle is striated with each elongated muscle fiber containing several nuclei. Skeletal muscles contract voluntarily; they move body parts. For example, they lift and lower arms and

legs on demand. Cardiac muscle is striated, but the elongated fibers are branched and fused with only one or two nuclei. Cardiac muscle contracts involuntarily for the heart to beat; it is a complex network that pumps blood continuously. Smooth muscle is not striated; it is made up of elongated spindle-like fibers, each with one central nucleus. Smooth muscle contracts involuntarily to move body organs; it contracts in the walls of the digestive tract to apply pressure to move food onward; it constricts arteries causing blood pressure to increase. • The respiratory system supplies oxygen to the blood and excretes carbon dioxide. The urinary system removes metabolic waste and excess materials from the blood, produces urine, and helps regulate blood chemistry. The endocrine system works with the nervous system to regulate metabolic activities and other body functions. 39.2 • In a negative feedback system, a change in a steady state triggers a response that counteracts, or reverses, the change. A sensor detects a change, a deviation from the normal condition, or set point. The sensor signals an integrator, or control center. Based on the input of the sensor, the integrator activates homeostatic mechanisms that restore the steady state. The response counteracts the inappropriate change, which restores the steady state. Unlike a negative feedback system, a positive feedback system does not reverse the change; a change in a steady state sets off a response that intensifies the changing condition. 39.3 • A cost of ectothermy is that temperature conditions, daily and seasonal, can limit an animal's activity. A benefit for ectotherms is that they survive on less food and convert more energy from food to growth and reproduction because they do not need to maintain a high metabolic rate. To adjust body temperature, ectotherms may move in or out of the sun to raise or lower temperature; they may migrate as seasons change or hibernate. • A cost of endothermy is that animals must expend considerable energy to maintain body temperature, even when inactive. Benefits of endothermy are a rapid response to internal and external stimuli, and a greater level of activity in cold weather. To help maintain body temperature, endotherms have structural adaptations (feathers, hair, insulating fat), behavioral adaptations, and several physiological mechanisms (shivering, sweating, panting, bringing heat to skin surface) mediated by nervous and endocrine systems.

See also Fig. 39-9.

Figure Questions

FIG. 39-5 Glucose concentration in your blood would increase. Your body would respond by negative feedback, releasing insulin into your blood to counteract the glucose until the steady state, or normal condition, is restored. **FIG. 39-7** If we could convert to a negative feedback system, the loss of blood and decrease in blood pressure would initiate factors that would slow the loss of blood by clotting at the wound site and constricting blood vessels.

Test Your Understanding

1. a 2. e 3. d 4. b 5. c 6. d

7.

See also Tables 39-1 and 39-2.

8. Cells → Tissues → Organs → Organ Systems. 9. Loss of epithelium would allow pathogens to enter the body, causing infection; loss of body fluids would lead to dehydration; skin damage could impact sensation and cause extreme pain. If the skin damage is not repaired and systems are not returned to the normal state, the patient could go into shock and may die. 10. Joint connections, body, and organ support would deteriorate, and the body would collapse. 11. Rapid breathing is typically shallow. Less oxygen would be inhaled and less carbon dioxide would be exhaled. As a result, carbon dioxide concentration would further increase, disrupting homeostasis even more. 12. Most animals are ectotherms; they do not use metabolic energy to maintain a constant body temperature. Compared to endotherms, ectotherms can survive on less food and they expend more energy on growth and reproduction. 13. A health care worker has an obligation to recommend any and all tests that may benefit the patient. A genetic test can provide information necessary for making medical decisions, especially if your family has a history of cancer. Knowing that you may be predisposed toward certain types of cancer can help you and your caregivers make educated decisions to improve your chances for survival.

Chapter 40

Checkpoint

40.1 • Invertebrates and vertebrates both have epithelial coverings that protect the body. The epithelial coverings may be specialized for gas exchange, secretion, or temperature regulation; skin may contain sensory receptors that obtain information from the surrounding environment. • Birds have feathers and mammals have hair, which provide insulation and help maintain body temperature; amphibians have skin that allows gas exchange and poison secretion; and mammals have claws and nails as well as sweat glands, oil glands, and sensory receptors. • Keratin gives skin mechanical strength and reduces water loss. • Melanin is a pigment that contributes to skin color and has a role in reducing ultraviolet radiation damage. **40.2** • The septa separating segments in the annelid worm allow the worm to move with more flexibility, as each segment is independent. • Advantages of the exoskeleton are to protect, transmit force, and reduce water loss; arthropods have modified parts of their exoskeleton that function as tools or weapons. The exoskeleton is a disadvantage for arthropods because their body continues to grow and they must molt, or shed their exoskeleton, which makes them weak and vulnerable to predation, while a new covering grows and hardens. • The main bones of the axial skeleton are the skull, sternum, rib cage, and vertebrae. The main bones of the appendicular skeleton are the

clavicle, scapula, humerus, radius, ulna, carpals, metacarpals, phalanges, pelvic girdle, femur, patella, fibula, tibia, tarsals, and metatarsals. • Osteoblasts build up bone by secreting the protein collagen that forms strong bone fibers; hydroxyapatite forms around the fibers and hardens into bone matrix. Osteoclasts break down (resorb) bone by secreting hydrogen ions that dissolve crystals and enzymes that digest collagen. Osteoblasts and osteoclasts work synergistically to shape bones.

40.3

See also Figs. 40-9 and 40-10. Actin is the thin filament; myosin is the thick filament. • For a muscle fiber to contract: (1) Acetylcholine, released by a motor neuron, binds with receptors on the muscle fiber, causing depolarization and generation of an action potential. (2) The action potential spreads through the T tubules, releasing calcium ions from the sarcoplasmic reticulum. (3) Calcium ions bind to troponin in the actin filaments, causing the troponin to change shape. The troponin pushes tropomyosin away from the binding sites on the actin filaments. (4) ATP (bound to myosin) is split, putting the myosin head in a high-energy state. Energized myosin heads attach to the exposed binding sites on the actin filaments, forming cross bridges that link the myosin and actin filaments. (5) After myosin attaches to the actin filament, P_i is released, triggering the power stroke. (6) During the power stroke, myosin heads pull the actin filaments toward the center of the sarcomere. ADP is released during the power stroke. (7) The myosin head binds a new ATP, which lets the myosin head detach from the actin. As long as the calcium ion concentration remains elevated, the new ATP is split and the sequence repeats. • ATP is the immediate source of energy for muscle contraction. The hydrolysis of ATP provides the energy to “cock” the myosin. Creatine phosphate is an intermediate energy storage compound for muscle tissue. Glycogen is the fuel stored in muscle fibers. • Skeletal muscle is striated, with each elongated muscle fiber contracting voluntarily to move body parts; arms and legs, for example, lift and lower on demand. Cardiac muscle is striated with elongated fibers that are branched and fused. Cardiac muscle contracts

involuntarily for the heart to beat; it is a complex tissue that pumps blood continuously. Smooth muscle is not striated; it is made up of elongated spindle-like fibers. Smooth muscle contracts involuntarily to move body organs; it contracts in the walls of the digestive tract to move food onward; it constricts arteries causing blood pressure to increase.

Figure Questions

FIG. 40-10 The greater the volume of myofibrils in a muscle fiber, the greater the force that the muscle can generate. **FIG. 40-11** If the body stopped producing acetylcholine, action potentials could not be generated. The person would quickly die because the muscles necessary for breathing could not contract.

Test Your Understanding

1. c 2. c 3. e 4. b 5. e 6. c 7. The high rate of metabolism in insect flight muscles is adaptive because a great amount of energy must be generated to support flight. This energy is generated by the numerous mitochondria in these muscles. Flight increases the opportunities to exploit additional habitats.

See also Fig. 40-9.

The resulting curve would be similar to the curve in Figure 40-13b, except there would be a third peak added to the graph slightly higher than the second twitch peak. 10. A skeletal muscle shifts function—agonist or antagonist—depending on what action is needed. If each muscle could only perform one function, twice as many muscles would be needed. 11. Muscles are attached to the bones by tendons; the muscles pull on the bones, which causes the bones to act as levers. As muscles weaken, or are not exercised, the bones also lose strength and weaken. 12. Benefits of the arthropod exoskeleton are protection, reduction of water loss, and modified parts that function as tools or weapons; a disadvantage of the exoskeleton is that as their bodies continue to grow, they must molt, making them weak and vulnerable to predation while a new covering grows and hardens. Advantages of the vertebrate skeleton are structural support for organs and locomotion, continued growth and change as the body ages, protection, transmission of muscle forces, and calcium storage for maintaining homeostatic levels of calcium in the blood. Disadvantages of the vertebrate skeleton are degenerative bone and joint diseases, and lack of external protection for many soft tissues. The insect skeleton is adapted to its terrestrial lifestyle: a light, but strong, chitin covering that resists water protects tissues; wings for flight, modified from thoracic exoskeleton; and a high degree of leverage for powerful muscle use. 13. Human muscle contraction and cellular movement in single-celled organisms both involve actin and myosin. 14. As science has elucidated how joints function, technology has used this knowledge to develop devices and materials to replace destroyed and deteriorated joints. Because humans live longer, joint replacement surgery has become common in developed countries to maintain peoples' active lifestyles. The return of wounded war veterans has driven new demands for high-tech, sophisticated replacement joints. Governments and corporations are investing in needed medical research and development in bioengineering and robot science.

Chapter 41

Checkpoint

41.1 • The sequence of processes that would allow you to escape the shark are: (1) reception by a sensory receptor; (2) transmission by afferent neuron; (3) integration by interneurons in CNS; (4) transmission by efferent neuron; (5) action by effectors: you yell for help and swim away from the shark. • After neural signals are integrated in the CNS, a neural message is transmitted from the CNS by efferent neurons to effectors. The actions of the effectors are the response to the stimulus.

41.2

See also Fig. 41-2. • A neuron produces and transmits an action potential; it is a cell of the nervous system, made of a cell body containing a nucleus and organelles, many branched dendrites extending out from the cell body, and a single long axon. A nerve is a bundle of several hundred axons wrapped in connective tissue. • Astrocytes provide physical support and nutrients for neurons, help regulate the composition of the extracellular fluid in the CNS, communicate with other neurons, and induce synapse formation. Microglia are specialized macrophages that mediate responses to injury and disease by moving to the affected area and removing bacteria and cellular debris. They also release signaling molecules that mediate inflammation and help regulate the number of neurons developing in the brain. **41.3** • Resting potential is mainly due to K^+ easily flowing out of ion channels. Sodium–potassium pumps move Na^+ out and K^+ into the neuron. For some neurons, resting potential is maintained at about -70 mV. • When the threshold level is reached, Na^+ channels open and Na^+ enters the neuron, causing depolarization. The action potential transmits a signal. After signal transmission, the neuron repolarizes; K^+ channels are opened, and K^+ diffuses out of the neuron; and the neuron then returns to its resting state. • An action potential is an all-or-none response; it is either initiated and continues (self-propagating) or there is no response. A graded potential is a local response that varies in magnitude depending on the strength of the stimulus and fades out within a few millimeters of its origin. • The benefits of saltatory conduction are that it is more rapid and requires less energy than continuous conduction. **41.4** • Biogenic amines have important roles in regulating mood. Dopamine also has a role in motor function. GABA functions as a widespread inhibitory neurotransmitter.

1. Action potential reaches synaptic terminals at the end of presynaptic neuron.
2. Calcium channels open in membrane, letting Ca^{2+} from the extracellular fluid enter the synaptic terminal.
3. Ca^{2+} cause synaptic vesicles to fuse with the plasma membrane and release neurotransmitter into the synaptic cleft.
4. Neurotransmitter binds with receptors on the membrane of postsynaptic neuron.
5. In response, specific ion channels open or close, resulting in either depolarization or hyperpolarization. When depolarization reaches threshold level, an action potential is generated in a postsynaptic neuron.

See also Fig. 41-11. • EPSPs are produced by a change in membrane potential that brings a neuron closer to the firing level. IPSPs are produced by a change in membrane potential that moves a neuron further from the firing level. **41.5** • Neural integration is the process of summing, or integrating, incoming signals. • Temporal summation occurs when repeated stimuli cause new EPSPs to develop before previous EPSPs have decayed. Spatial summation occurs when several closely spaced synaptic terminals release neurotransmitters simultaneously, stimulating the postsynaptic neuron at several different places. • In vertebrates, most neural integration takes place in the CNS (the brain or spinal cord).

See also Fig. 41-13.

Figure Questions

FIG. 41-8 Because tetrodotoxin blocks K^+ channels, it would not let the neuron repolarize. **FIG. 41-10** In multiple sclerosis, an autoimmune response destroys and scars myelin along nerves, causing gaps in the myelin covering; this lack of myelin slows or stops the transmission of neural impulses; it can also lead to abnormal nerve signaling (“cross-talk” between neurons). **FIG. 41-11** The neurotransmitter would not be able to bind; the ion channels would not open or close, so no action potential would be generated.

Test Your Understanding

1. c 2. d 3. a 4. c 5. d 6. b 7. See Fig. 41-11c.

See also Fig. 41-11c. The antidepressant/spheres could block reuptake of the neurotransmitter into the presynaptic neuron.

9. (a) Na^+ ions entering the postsynaptic neuron cause a graded depolarization, or EPSPs. (b) K^+ diffusing out of a postsynaptic neuron cause IPSPs. (c) Cl^- entering a postsynaptic neuron would produce IPSPs. 10. The acetylcholine affects the skeletal and cardiac muscle differently because of the different chemical composition of the two muscles. 11. A person could make future plans, change lifestyle, and obtain help earlier if he/she had a higher risk for AD and knew about the potential risk. Psychological care would need to partner with medical care for the future AD patient. 12. Diseases related to these neurotransmitters could be studied in actual cells as they are produced, and cells could be engineered to provide neurotransmitters for therapeutic reasons. 13. Convergent circuits (signals from many neurons sent to a few) and divergent circuits (signals from one neuron sent to many others) allow for greater neural flexibility and control of stimuli/responses to the environment.

Chapter 42

Checkpoint

42.1 • The cerebral ganglia of some arthropods differ from the ganglia of flatworms in that the arthropod ganglia have specific functional regions. These areas are specialized for integrating information transmitted to the ganglia from sense organs. • Trends in the evolution of nervous systems include: the number of nerve cells increased; nerve cell bodies became concentrated to form a brain and ganglia; neurons formed nerves and nerve cords; neurons became specialized to perform specific functions; and the number of interneurons and complex synaptic contacts increased. • With cephalization, sense organs became concentrated at the front end of the body; this allows the animal to find food and detect enemies and mates more effectively. With the brain located close by, responses can be rapid.

See also Fig. 42-4. • The CNS consists of the brain where most decisions are made and the spinal cord, which integrates some information itself, and also transmits information from afferent neurons to the brain and from the brain to efferent neurons. The PNS consists of the sensory receptors, the afferent nerves that transmit signals from the sensory receptors to the CNS, and the efferent neurons that transmit signals from the CNS to the muscles and glands. 42.3 • The vertebrate embryonic forebrain subdivides to form the telencephalon, which gives rise to the cerebrum and olfactory bulbs, and to the diencephalon, which gives rise to the thalamus and hypothalamus. The midbrain gives rise to the superior colliculi and the inferior colliculi. The hindbrain gives rise to the cerebellum, pons, and medulla. The cerebrum is the center of intellect, memory, and language, and controls sensory and motor functions. The thalamus is a relay center for motor and sensory messages. The hypothalamus is a major coordinating center for regulating autonomic and somatic responses. It controls body temperature and regulates appetite and water balance. The hypothalamus is important in emotional and sexual responses, and is the link between the

nervous and endocrine systems; it also produces certain hormones. The superior colliculi in the midbrain are centers for visual reflexes, and the inferior colliculi are centers for auditory reflexes. The cerebellum regulates motor coordination, muscle tone, posture, and equilibrium. It is important in planning and executing voluntary movements. The pons connects various parts of the brain with one another, and contains respiratory and sleep centers. The medulla contains centers that regulate respiration, heartbeat, and blood pressure. Other reflex centers in the medulla regulate activities such as swallowing, coughing, and vomiting. • The midbrain is the most prominent part of the amphibian brain, and it serves as the main association area. In mammals, the cerebrum is the largest, most complex part of the brain; it serves as the main association area. The cerebellum is also much larger in the mammalian brain than in the amphibian brain. 42.4 • The CNS is encased in bone and covered by three layers of connective tissue, the meninges (dura mater, arachnoid, pia mater). The CNS is also protected by the shock-absorbing cerebrospinal fluid. • The spinal cord transmits information to and from the brain and controls many reflex actions.

See also Figs. 42-10a and 42-11a. • The amygdala, part of the limbic system, filters incoming information and evaluates threat. When it perceives danger, the amygdala signals other parts of the brain. Following a traumatic experience, the amygdala may become hypersensitive to possible danger and may over-respond to harmless “triggers.” • Learning depends on synaptic plasticity, the ability of synaptic connections to change in response to experience. LTP changes the strength of a synaptic connection. NMDA receptors respond to the neurotransmitter glutamate by opening Ca^{2+} channels. Calcium ions act as second messengers that initiate long-term changes ultimately responsible for LTP. Gene expression and protein synthesis take place during the process of establishing long-term memory. (See Fig. 42-16.) **42.5** • The somatic division of the PNS innervates skeletal muscles and helps maintain posture and balance. The autonomic division of the PNS helps maintain homeostasis in the internal environment; its effectors are smooth muscle, cardiac muscle, and glands. • In general, the sympathetic system stimulates organs to mobilize energy, e.g., it speeds the heart; the parasympathetic system has the opposite effect. Typically, it stimulates organs to conserve and restore energy, e.g., it slows the heart. Sympathetic preganglionic neurons secrete acetylcholine and postganglionic neurons release norepinephrine. Both preganglionic and postganglionic parasympathetic neurons secrete acetylcholine. **42.6** • Alcohol is a CNS depressant;

antipsychotic drugs block dopamine receptors and have a calming effect; many SSRI antidepressants elevate mood by blocking serotonin reuptake; amphetamines stimulate release and block reuptake of dopamine and norepinephrine; opiates inhibit dopamine reuptake; and MDMA is a CNS stimulant. (See Table 42-4.)

Figure Questions

FIG. 42-6 During future evolution, the cerebellum and other motor areas of the brain may become smaller because physical activity may continue to decline. Scientists may interfere with evolution by using genetic engineering and technology to produce brains that function more effectively into old age (that is, without cognitive decline); and they may also develop brains with larger, more complex frontal lobes. **FIG. 42-16** Calcium ions activate pathways that lead to LTP. For example, Ca^{2+} activate a pathway leading to insertion of more AMPA receptors in the postsynaptic membrane; more AMPA receptors increase sensitivity to glutamate, resulting in more EPSPs. The EPSPs strengthen the synapse, maintaining the LTP.

Test Your Understanding

1. b 2. c 3. d 4. e 5. b 6. a 7. a

8.

See also Fig. 42-11a. 9. During the evolution of the vertebrate brain, there has been a trend toward greater complexity, particularly of the cerebrum and cerebellum. 10. Parents can stimulate their child's intellectual development by exposing the child to a wide variety of experiences from a very early age and by giving the child the opportunity to manipulate objects, including electronic devices such as computers. Providing a calm, safe environment enhances learning. 11. The limbic system would quickly assess the danger and send signals to other parts of the brain that would initiate protective action (e.g., running away). 12. The presence of CREB in diverse animals suggests a common ancestor (and that common pathways developed for learning and memory). 13. Because genes are activated during information processing (a critical measure of intelligence), and because genes are inherited, intelligence depends, at least in part, on inheritance of genes that code for information processing.

Chapter 43

Checkpoint

43.1 • A receptor potential is a change in membrane potential; it is a graded response in which the magnitude of change depends on the strength of the stimulus. In contrast, an action potential is generated only when a neuron becomes sufficiently depolarized to reach its threshold level. In a sensory neuron, receptor potentials depolarize the neuron to threshold level, generating

an action potential that transmits the signal to the CNS. • As you continue to hike, your perception of the odor will quickly decrease as sensory adaptation occurs. (The frequency of action potentials decreases, and decreases in neurotransmitter release may occur at the synapses.) • Sensory information is initially integrated in the receptor where receptor potentials produced by various stimuli are integrated by summation. However, integration occurs mainly in the spinal cord and at various locations in the brain, which selects, interprets, and organizes sensations and then converts them to perceptions of stimuli. • Refer to Table 43-1: Classification of Receptors by Type of Energy They Transduce. **43.2** • Mosquitos have thermoreceptors, which can locate an endothermic host. Snakes use thermoreceptors to locate prey or to detect predators. Mammals have thermoreceptors, which detect outside environmental temperature changes. Mammals also have thermoreceptors in the hypothalamus to detect internal changes in temperature and receive and integrate information from receptors on the body surface. **43.3** • Electroreceptors sense differences in electrical potential to detect electric fields for locating prey and for navigation. Electroreceptors also aid in communication, as males and females have different frequencies of electric discharge. • Some animals use electromagnetic reception to facilitate orientation and navigation. **43.4** • Mechanical nociceptors respond to strong tactile stimuli such as cutting, crushing, or pinching; thermal nociceptors respond to temperature extremes (above 45°C or below 45°C); polymodal nociceptors respond to a variety of damaging stimuli, including certain chemicals. • Substance P activates

interneurons that transmit the pain message to the opposite side of the spinal cord. Endorphins bind with opiate receptors on the terminals of sensory neurons in the spinal cord to inhibit release of substance P, stopping transmission of the pain signal. **43.5** • Mechanoreceptors help to maintain balance and body position as you walk. Tactile receptors aid orientation and the contact you have with the floor. Proprioceptors help you perceive movement of your legs, arms, and head as you move, and they help maintain balance. • The vestibular apparatus helps maintain equilibrium. The three semicircular canals provide information about turning movements, called angular acceleration. • The sequence of events involved in hearing are as follows: sound waves enter external auditory canal; tympanic membrane vibrates; malleus, incus, and stapes amplify vibrations; oval window vibrates; vibrations are conducted through fluid; basilar membrane vibrates; hair cells in organ of Corti are stimulated; cochlear nerve transmits impulses to the brain. **43.6** • Olfaction and gustation are closely related functions; they occur through chemoreceptors, which allow animals to detect substances in food, air, and water. Information from both systems is sent to the limbic system in the brain. **43.7** • The insect compound eye is structurally and functionally different from the vertebrate eye. The insect eye has many faceted units called ommatidia, each of which consists of a cornea and lens unit made up of photoreceptors called retinular cells. The insect eye can form only coarse mosaic images, and it compensates by superbly detecting movement. Because an insect's eye is sensitive to wavelengths of light in the range from red to ultraviolet (UV), it can see UV light well. The vertebrate eye has an adjustable lens, which can be focused for different distances; an iris, which regulates the amount of light entering the eye; and a retina made up of rod and cone photoreceptor cells. The vertebrate eye can adjust focus to see sharp images. The vertebrate eye is sensitive to wavelengths ranging from red to violet. • When light strikes rhodopsin, light energy is transduced. Refer to Figure 43-22 for a description of the signal transduction pathway. • Light passes through the cornea and then through aqueous fluid, through the lens and through the vitreous body. An image forms on photoreceptor cells in the retina, signaling bipolar cells and then ganglion cells. The optic nerve transmits signals to the thalamus and visual areas of the cerebral cortex. • All visual images constructed by the retina are integrated and interpreted in the brain.

Figure Questions

FIG. 43-9 The utricle and saccule would not be able to sense changes in head position and would have no function in a weightless environment. **FIG. 43-10** When you reverse your spinning direction, the endolymph flows in the opposite direction. If you then stop spinning, the position of the stereocilia would return to normal, and action potentials signaling circular rotation would stop. **FIG. 43-11** If the basilar membrane were

damaged at its higher, stiff end, the individual would no longer be able to hear high frequency sounds. If the basilar membrane were damaged at its wide, flexible end, the individual would no longer be able to hear lower frequency sounds. (High frequency hearing is greatly impacted by excessive exposure to high frequency and high impact [loud] sounds common to our environment, such as loud music, machinery, or phones, which damage and destroy cilia.) **FIG. 43-20** Cones, which are responsible for color vision, respond best in daylight. We depend on rods to detect shape and movement in dim light.

Test Your Understanding

1. c 2. d 3. a 4. d 5. b 6. c 7. Rods and cones → bipolar cells → ganglion cells → optic nerve. 8. Although there are only a few types of taste receptors, each different substance sensed by taste receptors is a unique combination of molecules with its own signature. 9. We distinguish quality and intensity of sensory information based on the destination of the sensory neuron (that is, to which structure is the information delivered?); total number of neurons transmitting the signal; total number of action potentials transmitted by the neuron; and frequency of the action potentials. 10. The same proteins in the photoreceptors of many diverse organisms indicate that opsins evolved early and the genes coding for them are highly conserved. 11. The rapid evolution of image-forming eyes and their presence in most animals was an advantage, or edge, for survival. Animals that could see better could detect prey or avoid capture and passed this genetic advantage to their offspring. Most animals without image-forming eyes were unable to compete and many became extinct. 12. Any answer is acceptable if a logical argument is presented.

Chapter 44

Checkpoint

44.1 • Gases are exchanged by diffusion in hydras and flatworms; earthworms have a closed circulatory system, and small blood vessels deliver blood to the body surface in every segment; gas exchange takes place through the body surface. In insects, gas is exchanged through a system of tubes that are separate from the circulatory system; frogs have a respiratory system with lungs for gas exchange. • In an open circulatory system, a heart pumps hemolymph into vessels that have open ends. The hemolymph bathes the cells directly, and then re-enters the circulatory system through openings in the heart (in arthropods) or through open-ended blood vessels (in mollusks). In closed circulatory systems, blood flows through a continuous circuit of blood vessels. The walls of capillaries are thin enough to permit diffusion of gases, nutrients, and wastes between blood in the vessels and the interstitial fluid that bathes the cells. • The vertebrate circulatory system transports nutrients from the digestive system

and from storage depots to each cell; transports oxygen from respiratory structures to the cells; transports metabolic wastes from each cell to organs that excrete them; transports hormones from endocrine glands to target tissues; helps maintain fluid balance; helps distribute metabolic heat within the body; and helps maintain appropriate pH. 44.2 • Alpha globulins include certain hormones, proteins that transport hormones, and other compounds, including prothrombin and HDL. Beta globulins include lipoproteins that transport fats and cholesterol and proteins that transport certain vitamins and minerals. The gamma globulin fraction of plasma contains antibodies. Globulins and albumins help regulate distribution of fluid between plasma and interstitial fluid. Plasma proteins help maintain the pH of the blood within a narrow range. • Red blood cells transport oxygen; neutrophils, the main phagocytic cells in the blood, ingest bacteria. • A shortage of fibrinogen in the blood would prevent clotting. 44.3 • Arteries transport blood away from the heart; veins transport blood toward the heart; and capillaries are the exchange vessels. • If arterioles could not constrict, the body could not regulate blood pressure; also, the body would not be able to regulate the amount of blood going to each tissue or organ. 44.4 • During the evolution of the vertebrate cardiovascular system, structural changes evolved that allow separation of oxygen-rich from oxygen-poor blood; most non-avian reptiles, all avian reptiles (birds), and all mammals have a double circuit of blood flow. In avian reptiles and mammals, the heart has four chambers: two atria and two ventricles. 44.5 • During cardiac conduction, the SA node initiates contraction → action potential spreads through atrial muscle fibers (atria contract) → action potential delayed briefly in AV node → action potential

spreads into AV bundle → right and left bundle branches → Purkinje fibers → conduct impulses to muscle fibers of both ventricles → ventricles contract. • When the mitral valve does not close completely, some blood leaks backward into the atrium when the ventricle contracts; less blood flows to the tissues of the body. As a result, the heart pumps harder. This condition can lead to congestive heart failure. • Cardiac output = stroke volume (100 mL per stroke) × heart rate (100 contractions/minute) = 10,000 mL/min (10 L/min). 44.6 • Arteriole constriction increases blood pressure. • Blood pressure in arteries is higher than blood pressure in veins. 44.7 • Blood flowing from the carotid artery to the superior vena cava passes through: carotid artery → capillaries in brain → jugular vein → superior vena cava. Blood flowing from the renal vein to the renal artery passes through: renal vein → inferior vena cava → right atrium → right ventricle → pulmonary arteries → pulmonary capillaries (in lungs) → pulmonary vein → left atrium → left ventricle → aorta → renal artery. • Recall that most veins conduct blood to larger veins or to the superior or inferior vena cava. The hepatic portal system is an exception. This vein transports nutrients from the intestine to the liver. In the liver, the hepatic portal vein branches into a network of hepatic sinuses from which nutrients leave the circulation and enter liver cells. The liver stores nutrients that are not immediately needed by other cells. The hepatic sinuses then merge to form hepatic veins. The sequence of blood flow: hepatic portal vein → hepatic sinuses (in liver) → hepatic veins.

44.8 • See figure below.

See also Figs. 44-19 and 44-20. • The lymphatic system collects excess interstitial fluid and returns it to the blood. 44.9 • Joe is at high risk for cardiovascular disease. • During development of atherosclerotic plaque, endothelial cells respond to oxidized LDLs by releasing compounds that attract monocytes. These white blood cells enter the tissues and trigger an inflammatory response. Cells of the immune system migrate to the area and produce substances that maintain chronic inflammation in the inner layer of the arterial wall. Some macrophages become foam cells, which stimulate the development of fatty streaks. These streaks may be the initial lesion in atherosclerosis.

Figure Questions

FIG. 44-6 Lymph vessels have very small dead ends that infiltrate most tissues in the body. They are one-way vessels that pick up fluid and deliver it into the blood circulation through two small ducts in the shoulder region. **FIG. 44-8** The separation of oxygen-rich blood from oxygen-poor blood in avian reptiles and mammals enables their cardiovascular systems to deliver more oxygen to their tissues. As a result, these animals can maintain a higher metabolic rate than other animals, allowing a constant high body temperature even in cold surroundings. **FIG. 44-11** When the SA node increases its rate of firing, the cardiac cycle speeds up accordingly. **FIG. 44-16** The left ventricle needs a thicker wall than the right ventricle because the left ventricle must contract strongly enough to pump blood at a higher pressure through the higher resistance and longer arterial system. If the right ventricle contracted that powerfully, the lung tissue would be damaged.

Test Your Understanding

1. a 2. d. 3. e 4. d 5. e 6. e 7. d 8. c

9.

A-70 / Appendix E

See also Fig. 44-6. The thick walls of arteries are adapted to the high pressure they must withstand. Compared to arterial walls, the walls of veins are thin. Capillary walls are only one cell thick, allowing nutrients, oxygen, and other substances to pass through them. 10. The heart rate is carefully regulated by sympathetic and parasympathetic nerves, which are controlled by a cardiac center in the brain stem. 11. The four-chambered heart allows efficient oxygenation of body tissues, which in turn allows these animals to be endothermic. 12. Fish have a single circuit of blood vessels. Blood leaving the heart passes through the gills, where it is oxygenated. 13. Blood vessels with atherosclerotic plaque deliver less oxygen to the tissues, including the heart itself. In ischemic heart disease, the heart muscle is not receiving enough oxygen, particularly during exercise or emotional stress. The remaining two parts of this question ask your opinion. As you reflect on the questions, consider the human misery caused by cardiovascular disease, as well as the monetary cost to society.

Chapter 45

Checkpoint

45.1 • Adaptive immunity consists of specific defenses that target specific macromolecules. In adaptive immunity, the body typically produces antibodies that recognize and bind to specific antigens. Also unlike innate immunity, adaptive immunity is characterized by immunological memory. • Like invertebrates, vertebrates depend on innate immunity for their initial defense against invading pathogens. Unlike invertebrates, vertebrates have highly developed adaptive immunity. **45.2** • The function of pattern recognition receptors is to recognize nonself molecules; these receptors recognize pathogen-associated molecular patterns (PAMPs). • If you had no NK cells, you would be much more vulnerable to virus infections and developing tumors. Macrophages are the main phagocytes in the body. If you had no macrophages, both your innate and adaptive immune systems would be severely impaired. • Cytokines are important signaling molecules with a wide variety of functions. For example, they enhance the inflammatory response, stimulate NK cell activity, and activate lymphocytes. Complement proteins destroy viruses and bacteria; they attract white blood cells to the site of infection; they enhance the inflammatory response.

See also Fig. 45-3. Main steps in the inflammatory response would include activation of macrophages and mast cells, vasodilation, increased capillary permeability, and increased phagocytosis. **45.3** • Cell-mediated immunity and antibody-mediated immunity are two types of adaptive immunity. Lymphocytes are the key cells in both. T cells (and APCs) are the main cells in cell-mediated immunity. T cells attack foreign cells, cancer cells, and body cells infected by invading pathogens. B cells are responsible for antibody-mediated immunity. B cells mature into plasma cells, which produce specific antibodies. • Antigen-presenting cells (APCs) activate T helper cells. Macrophages, dendritic cells, and B cells function as APCs. • A kidney transplant from a first cousin has a higher probability of success than a transplant from an unknown donor because first cousins are more likely to have more HLA alleles in common. (First cousins have 12.5% of their genes in common.) **45.4** • APCs activate T_H cells (and also activate T_C cells). Activated T cells divide by mitosis to form a clone of activated cells. T_H cells release cytokines that activate T_C cells (and macrophages). T_C cells release proteins that destroy infected cells. **45.5** • See highlighted sequence summary of events on page 974.

See also Figs. 45-8 or 45-9. Antigen-antibody complexes: inactivate pathogens or their toxins; stimulate phagocytes to ingest pathogens; IgG and IgM activate the complement system. • Immunological memory depends on memory B cells and memory T cells; after an infection, these cells remain strategically stationed in the body and can respond rapidly to antigens they have encountered before. • Passive immunity is borrowed immunity; memory cells are not produced and its effects are temporary. **45.6** • Some types of cancer cells can block T_C cells. Other cancer cells decrease their expression of class I MHC molecules, preventing T_C cells from recognizing them. Still others do not produce co-stimulatory molecules needed to activate T_C cells. • HIV enters the body through the mucosa that lines passageways into the body. A protein on the outer envelope of the virus attaches to CD4 on the surface of T_H cells. HIV enters the T_H cell and is reverse-transcribed to produce DNA. Its DNA is then incorporated into the host genome. The virus reproduces itself, causing death of the host cell. Innate immune responses include production of antimicrobial peptides and action by NK cells, dendritic cells, and the complement system. Adaptive immune responses include activation and mobilization of T_C cells. • An autoimmune disease is a failure in self-tolerance. Antibodies and T cells attack the body's own tissues. Viral or bacterial infection often precedes the onset of an autoimmune disease. Molecular mimicry has evolved in some pathogens; these pathogens trick the body by producing molecules that look like self-molecules. Immune cells may not discriminate and may attack the body's similar molecules. Overactivation of cells of the immune system can result in inflammation and autoimmune disease.

1. Previous exposure to pollen causes plasma cells to make pollen-specific IgE.

2. IgE combines with mast cell receptors in lining of nasal passages.

3. Pollen is inhaled.

4. Allergen combines with region of IgE on surface of sensitized mast cell.

5. Mast cell releases histamine and other chemicals.

6. This release causes increased vasodilation and increased capillary permeability. Symptoms result: edema, redness, constriction of respiratory passageways, mucus.

See also Fig. 45-17. • When tissue from a donor is transplanted to the body of another person, several of the HLA antigens are likely to be different. The recipient's T_H cells and T_C cells recognize the graft as nonself (i.e., foreign) and launch an immune response known as graft rejection. T_C cells, the complement system, and cytokines secreted by T_H cells attack the transplanted tissue and can destroy it within a week.

Figure Questions

FIG. 45-3 Several signs of infection would be evident due to the inflammatory response. The foot would be swollen, red, and warm to the touch at and near the site of the puncture. You would experience pain from your foot and might have a low-grade fever. Pus might be seeping from the wound. **FIG. 45-5** The malignant cells would crowd out other cells in the bone marrow, severely slowing the production of antigen-presenting cells and lymphocytes. **FIG. 45-6** Macrophages, dendritic cells, and B cells function as antigen-presenting cells (APCs). **FIG. 45-8** Immunity would be depressed if T_C cells collected in the lymph tissues as plasma cells do. T_C cells are the cellular infantry; they must spread out strategically to discover and destroy incoming pathogens. In contrast, plasma cells remain in the bone marrow and release antibodies into the circulation.

Test Your Understanding

1. b 2. c 3. e 4. c 5. a 6. e 7. c 8. b 9. a 10. d

11.

See also Fig. 45-7, step 3. This diagram shows a T_H cell activating a B cell, which then divides, producing two B cells. 12. Specificity helps make the immune system very efficient. T cells and antibodies are produced that are highly specific for destroying the particular pathogens that invade the body. Diversity gives the immune system the capability of protecting the body from almost any new pathogen that invades (see Fig. 45-11). Immunological memory allows the immune system to “remember” each type of pathogen against which it has already launched an immune response. When it encounters the same pathogen again, the immune system launches a rapid attack. 13. Macrophages are important in both innate and adaptive immune responses. Reduction in macrophages would critically decrease the body’s ability to launch an immune response. A significant decrease in macrophages would probably have a more serious negative impact than a decrease in memory B cells because macrophages are first responders. The body could compensate for a decrease in memory B cells by launching a primary immune response. 14. In kindergarten, John has been immunized so is unlikely to develop measles again. Jack will likely develop measles, and his body will develop immunity to the measles virus. Five years later when Judy (who has the measles virus) sneezes on both of them, it is improbable that either John or Jack will develop measles because both of them have immunological memory of the virus. 15. These facts suggest that the genes that encode the enzymes necessary for antibody diversity, an important aspect of adaptive immunity, are very old and that echinoderms and jawed vertebrates share a common ancestor. 16. In forming your opinion, you might consider how we could use technology to better inform the millions of people living in poverty in low-income countries. Also, how could we more rapidly apply new technology to the development of new vaccines and treatments?

Chapter 46

Checkpoint

46.1 • Air has a higher concentration of oxygen; oxygen diffuses faster in air; and animals that breathe air expend significantly less energy to obtain oxygen than animals in an underwater habitat. **46.2** • Flatworms can depend on diffusion for gas exchange, but the larger tadpole body requires a respiratory system for gas exchange. • An earthworm exchanges gases through the body surface. A grasshopper exchanges gases through a system of tracheal tubes, also called tracheae. Fish exchange gases through internal or external gills. Birds exchange gases with a complex, and very efficient, system of lungs and air

sacs. • The countercurrent exchange system increases the efficiency of gas exchange because much more oxygen is able to diffuse into the blood when the blood flows through the capillaries in the opposite direction compared with the water. **46.3** • In mammals, air enters through the nostrils, then passes through the nasal cavities, pharynx, larynx, trachea, bronchi, then bronchioles, and lastly enters the alveoli (air sacs). • Gas exchange takes place in the alveoli. Oxygen concentration is lower in the alveoli than in atmospheric air because cells of the body use oxygen during cellular respiration; carbon dioxide concentration is higher in the alveoli than in atmospheric air because carbon dioxide is produced during cellular respiration. • Increased carbon dioxide in the blood lowers the pH (blood becomes more acidic). When blood is more acidic, hemoglobin unloads oxygen more readily. • Breathing would increase as more oxygen is required for cellular respiration. You would also breathe harder to increase ventilation to dispose of excess carbon dioxide. Chemoreceptors in the walls of the aorta and carotid arteries sense lower blood pH, which stimulates chemoreceptors to up-regulate breathing. As the lungs remove carbon dioxide, the blood pH returns to normal and homeostasis is restored. **46.4** • Hairs in the nose and the moist ciliated lining traps inhaled particles. The ciliated mucous lining of the airway also traps inhaled particles. Bronchial constriction increases the probability that inhaled particles will land on the mucous lining of the bronchioles, rather than enter the more delicate tissues of the lungs. • When the respiratory defense system is overwhelmed by pollutants, diseases such as chronic bronchitis, pulmonary emphysema, COPD, and lung cancer are more likely to occur.

Figure Questions

FIG. 46-2 The highly efficient tracheal system of insects delivers oxygen to all parts of the body. **FIG. 46-3** The countercurrent flow functions in similar ways for carbon dioxide removal and oxygenation; carbon dioxide is transferred from blood in the capillaries to the surrounding water at the same time oxygen is transferred from the water to the blood in capillaries. **FIG. 46-7** The capillary walls are only one cell thick; millions of pulmonary capillaries act as an interface to readily exchange gases in the alveoli. **FIG. 46-11** If the carbonic anhydrase enzyme were inhibited, carbon dioxide would build up in the red blood cells; net diffusion of carbon dioxide from the body cells into the red blood cells would slow and then cease.

Test Your Understanding

1. a 2. a 3. b 4. c 5. d 6. e 7. c 8. e 9. c 10. d

11.

See also Fig. 46-6. 12. Having millions of alveoli immensely increases the surface area for gas exchange. 13. Strenuous muscle activity would increase acidity of the blood and hemoglobin would unload oxygen more readily. The oxygen-hemoglobin curve would shift to the right. 14. On land the gills' extensions would dry up and collapse, blocking the surface area for gas exchange. A terrestrial animal with gills would suffocate and die. 15. It would be advantageous for fish that live at the land-water interface to have gills and lungs. The lungs of modern fish serve as swim bladders to control buoyancy. 16. Whales and dolphins were originally land mammals with lungs; when they returned to the sea, they continued to require air to breathe. 17. Further increasing tobacco taxes could encourage users to seek help for their expensive addiction; the collected taxes could pay for addiction treatment and research. Also, reducing and gradually eliminating places to smoke may continue to be an effective method to curtail smoking.

Chapter 47

Checkpoint

47.1 • Some predators have tentacles, claws, or poison glands. Carnivorous mammals have canine teeth for stabbing prey; their pointed incisors and canines are adaptations for ripping flesh. • Flatworms have a gastrovascular cavity with only one opening; digestion is completed intracellularly within food vacuoles. Earthworms have a complete digestive tract that

extends from a mouth to an anus; some regions of the digestive tract are specialized to perform specific food-processing functions. • Various regions are specialized to perform specific functions, and different functions can be carried on simultaneously—for example, at the same time food is being digested in the stomach, nutrients can be absorbed in the small intestine and wastes can be eliminated from the large intestine. **47.2** • Mouth—mechanical digestion; enzymatic digestion of starches begins; pharynx—food swallowed; esophagus—peristaltic contractions move food to the stomach; stomach—mechanical digestion and enzymatic digestion of proteins; small intestine—digestion and absorption of nutrients; large intestine—absorbs water and sodium from the chyme, and certain bacteria that are part of the intestinal biome produce vitamin K and certain B vitamins; anus—opening for elimination of wastes. • Rugae increase the surface area in the stomach; villi increase the surface area in the small intestine. • Trypsin digests proteins and polypeptides; bile salts mechanically digest fats; gastrin stimulates gastric motility and stimulates gastric glands to secrete pepsinogen and HCl; and lacteals, the central lymph vessel in each villus, absorb chylomicrons (fat droplets).

See also Fig. 47-4. **47.3** • Carbohydrates, fats, proteins, vitamins, minerals. • Glucose provides energy; essential amino acids are required to synthesize proteins. • LDLs deliver cholesterol to the cells; they are the main source of the cholesterol that builds up in the walls of arteries, causing cardiovascular disease.

47.4 • Energy input = Energy output

When energy input equals energy output, body weight remains constant; when energy input is less than energy output, body weight decreases; and when energy input is greater than energy output, body weight increases. • BMI is an index of weight in relation to height. • Melanocortins suppress appetite, resulting in decreased food intake and weight loss; NPY stimulates appetite; and ghrelin stimulates appetite by activating neurons in the hypothalamus to produce NPY. Leptin signals the hypothalamus about the status of energy stores in adipose tissue. It slows the release of NPY and stimulates release of melanocortins.

Figure Questions

FIG. 47-4 The esophagus would need to be connected to the duodenum. **FIG. 47-9** Lymph tissue in the wall of the gastrointestinal tract is rich in macrophages, T cells, and other cells of the immune system. These cells are closely positioned to destroy pathogens that enter the body in contaminated food or water. **FIG. 47-10** If gluten remains part of the diet, the mucosa of the small intestine becomes damaged and the villi cannot absorb enough nutrients. This can lead to malnutrition.

Test Your Understanding

1. c 2. d 3. d 4. e 5. b 6. d 7. a 8. b 9. c 10. c

11.

See also Fig. 47-10. 12. You could include an experimental and a control group with about 20 mice in each group. Both groups would be fed the same diet *except* the diet of the experimental group would lack pyridoxine. You could weigh each mouse each day and also note specific health factors, including condition of skin, GI tract function, and presence of convulsions. Compare the health of the two groups of mice after a set number of weeks. 13. In their inactive form, proteolytic enzymes do not digest the lining of the GI tract. 14. You could examine the animal's tooth structure, and look for other clues, e.g., sharp claws, size of jaws. 15. Identifying and understanding the actions of the many hormones and other signaling molecules that regulate energy metabolism might lead to the development of new compounds that could inhibit appetite-stimulating compounds or stimulate appetite-suppressing compounds in the body. A cure for obesity would lead to a healthier society and also save billions of dollars each year in health care costs.

Chapter 48

Checkpoint

48.1 • Osmoregulation maintains salt and water concentrations within homeostatic limits. • Excretory systems help maintain homeostasis through osmoregulation and excretion of metabolic wastes. **48.2** • Some aquatic animals excrete ammonia; insects, certain reptiles, and birds excrete uric acid; urea is the principal nitrogenous waste excreted by amphibians and mammals. • Excretion of nitrogenous wastes as uric acid conserves water in terrestrial animals. Uric acid and urea are less toxic than ammonia. The body can store concentrated urea without causing damage to tissues. **48.3** • Nephridia consist of simple or branching tubes that open to the outside of the body through pores. The protonephridia of flatworms and nemertean have blind ends that consist of flame cells with cilia. The cilia propel fluid through the tubules. The metanephridia of annelids and mollusks are open at both ends. As fluid moves through the tubule of a nephridium, water and certain other substances (e.g., glucose) are reabsorbed by capillaries, leaving the waste to be excreted. The Malpighian tubules of insects excrete wastes more selectively than nephridia. Malpighian tubules are slender extensions of the gut wall; they have blind ends that extend into the hemocoel. Cells of the tubule wall actively transport uric acid, potassium ions, and some other substances from the hemolymph into the tubule. Malpighian tubules empty into the gut. Water, some salts, and other solutes are reabsorbed into the hemolymph by a specialized epithelium in the rectum. **48.4** • Marine fishes lose water osmotically and take in salt. To compensate they drink and retain sea water. Specialized cells in their gills excrete salt. Marine cartilaginous fishes retain a high urea concentration, which makes their body fluids hypertonic to sea water, so there is a net inflow of sea water. Freshwater fishes are hypertonic to the fresh water around them, and water continuously moves into the body. Their kidneys excrete large amounts of dilute urine. These fishes also lose salts by diffusion through their gills into the surrounding water. Special gill cells actively transport salt back into the body. • Marine birds ingest sea water and take in a lot of salt in their food. Glands in their heads excrete salt in response to osmotic stress. Marine mammals ingest sea water along with their food. Their kidneys produce concentrated urine, saltier than sea water. Terrestrial birds and mammals have efficient kidneys that conserve water. Birds conserve water by reabsorbing water from the intestine and by excreting uric acid. Mammalian kidneys produce hypertonic urine. **48.5** • The liver produces urea; the kidneys produce urine; the urinary bladder stores urine; and the urethra conducts urine out of body. • Filtration is the job of the glomerulus; reabsorption is the job of the renal tubules; and secretion takes place in the renal tubules and collecting ducts. • Bowman's capsule → proximal convoluted

tubule → loop of Henle → distal convoluted tubule → collecting duct → ureter → urinary bladder. See also Figs. 48-8 and 48-10. • The main actions of the renin–angiotensin–aldosterone pathway are to increase sodium reabsorption, which raises blood pressure. Angiotensin II also raises blood pressure directly by constricting blood vessels, and it stimulates the posterior pituitary to release ADH. In contrast, ANP decreases blood pressure by increasing sodium excretion, dilating afferent arterioles, and inhibiting aldosterone secretion.

Figure Questions

FIG. 48-5 If a shark were swimming in fresh water, its kidneys would need to work harder in order to produce a large volume of dilute urine to compensate for the increase in water entering the shark through osmosis. **FIG. 48-10** Mild dehydration would affect kidney function by reducing the volume of the blood plasma. More water would need to be reabsorbed, and a low volume of more concentrated urine would be produced. **FIG. 48-14** ADH increases water reabsorption, which increases blood volume. By this mechanism, ADH raises arterial blood pressure.

Test Your Understanding

1. c 2. d 3. e 4. d 5. a 6. a 7. c 8. d 9. e 10. b 11. e

12.

See also Fig. 48-9a. 13. In someone with diabetes mellitus, the concentration of glucose in the blood exceeds its tubular

transport maximum. The excess glucose that cannot be reabsorbed is excreted in the urine. Because the urine is more hypertonic, more water enters it by osmosis. The urine volume increases. 14. Dehydration is a familiar example of a human osmoregulatory challenge. Dehydration results in a lower blood volume and resulting lower blood pressure. These events stimulate increased secretion of ADH and aldosterone. Decreased blood pressure also stimulates renin release, which leads to increased angiotensin II. These hormones increase blood pressure. 15. In planaria, when the salinity of the surrounding water decreases, the number of protonephridia increase. When its environment is less salty, more water enters the planarian's body by osmosis. The protonephridia expel the excess water. 16. The kangaroo rat must conserve water by producing a very low volume of urine. 17. The structure and function of the vertebrate kidney has evolved along with vertebrate groups. For example, marine bony fishes have very small glomeruli (some have none at all). They drink sea water and excrete salt through specialized cells in their gills. Their kidneys excrete very little urine. Mammalian kidneys are more efficient than bird kidneys; they can produce more concentrated urine. There is a correlation between the length of the loop of Henle and the ability to concentrate urine. 18. Answers will vary based on your opinion.

Chapter 49

Checkpoint

49.1 • Target cells are cells that are influenced by a particular hormone and have specific binding receptors. • The nervous and endocrine systems work together to maintain homeostasis. Neurons help regulate many endocrine responses; for example, sympathetic nerves regulate the adrenal medulla. Endocrine glands work together with the nervous system to cope with stress and in regulating many other body functions. • When calcium concentration in the blood decreases below its homeostatic level, a negative feedback system is engaged; the parathyroid glands release more parathyroid hormone, returning the calcium concentration to the homeostatic level. • The four major chemical groups of hormones are fatty acid derivatives, which include prostaglandins; steroid hormones such as cortisol; amino acid derivatives such as epinephrine; and peptide hormones such as glucagon.

49.2 • **Classical endocrine signaling**

Neuroendocrine signaling

See also Figs. 49-3a and b. • In autocrine signaling, a hormone acts on the cells that produce it, while in paracrine signaling, a hormone diffuses through interstitial fluid and acts on nearby target cells. • Prostaglandins modify cyclic AMP levels and interact with other hormones to regulate various metabolic activities. 49.3 • Receptors convert an extracellular hormone signal into an intracellular signal that affects some cell process. Peptide hormones do not enter the cell; they serve as first messengers and relay information to a second messenger. The second messenger signals effector molecules that carry out the action. • Steroid hormones are relatively small, lipid-soluble molecules that easily pass through the plasma membrane of the target cell. Peptide hormones, not lipid soluble, bind to specific cell-surface receptors in the plasma membrane. • Many protein hormones bind to G protein-linked receptors. The receptor activates a second messenger such as adenylyl cyclase, which then catalyzes the conversion of ATP to cAMP. This second messenger relays the signal, activating a protein, such as protein kinase, which leads to a response or change in the cell. 49.4 • Four actions of hormones in invertebrates are helping to regulate metabolism, growth and development, reproduction, and molting. • Juvenile hormone suppresses metamorphosis at each larval molt. With each successive molt, the level of juvenile hormone decreases. 49.5 • The hypothalamus is the link between the nervous and endocrine systems because it regulates endocrine activity and connects both systems anatomically. The anterior pituitary regulates growth and other endocrine glands. The posterior pituitary secretes oxytocin and antidiuretic hormone produced by the hypothalamus.

See also Fig. 49-10a. • The beta cells in the pancreas would secrete insulin, lowering blood glucose concentration. Insulin decreases blood glucose concentration, while glucagon increases it; both are regulated by negative feedback systems. • The adrenal glands would be triggered to release large amounts of epinephrine and norepinephrine so you could

think quicker, fight harder, and run faster to escape the reptilian jaws. • The adrenal medulla is regulated by the hypothalamus and sympathetic nervous system, while the adrenal cortex is regulated by negative feedback involving the hypothalamus and adrenocorticotropic hormone (ACTH).

Figure Questions

FIG. 49-4 Because there would be fewer receptors that could become activated, specific protein synthesis would be slowed.

FIG. 49-5 Less cAMP (the second messenger) would be produced, so fewer proteins would be activated, and the effect of the hormone would be decreased. **FIG. 49-13** Less glucagon would be secreted and the glucose concentration in the blood would decrease below normal. The person would experience hypoglycemia.

Test Your Understanding

10. See also Fig. 49-13.

11. Cells require glucose for cellular respiration. There are many challenges to glucose homeostasis, and multiple hormones work together to regulate carbohydrate metabolism. For example, when the body is under stress, cortisol promotes conversion of other nutrients to glucose. 12. The brain does not store glucose; however, neurons require a steady supply of this fuel molecule. When neurons in the brain are deprived of glucose, the brain is not able to function. The individual may pass out, or if the situation is prolonged, could become comatose or die. 13. Receptors only bind with specific hormones. An advantage of having complexity in hormone action is the precision that is achieved among and between different body systems and regulatory functions. 14. The receptor for aldosterone may have been a receptor for some ancient, no longer present, similar hormone before aldosterone evolved. 15. Humans have evolved over tens of thousands of years (or longer) to store fat and consume a great deal of food when it is available. This physiological characteristic cannot be rapidly changed, but the dilemma can be addressed psychologically and socially. Scientists and doctors can partner with educators to facilitate public understanding about healthy food consumption, physical exercise, and our human proclivity to stuff ourselves with fatty, sugary foods. More technologies can be developed to stimulate pleasurable physical exercise and to retool the food-processing industry without sacrificing taste.

Chapter 50

Checkpoint

50.1 • In budding (e.g., in cnidarians), a small part of the parent's body separates from the rest and develops into a new individual. In fragmentation, the body of the parent breaks into several pieces; each piece regenerates the missing parts and develops into a new animal. In parthenogenesis, an unfertilized egg develops into an adult animal. • Compared with sexual reproduction, asexual reproduction is the fastest and most efficient way to reproduce. For example, each cell can produce

two new cells. The disadvantage of asexual reproduction is that the offspring has all of the same genes as the single parent (except for mutations); as a result, there is a lack of variability in the population. **50.2** • The testes produce sperm and the male hormone testosterone. • Seminiferous tubules → epididymis → vas deferens → ejaculatory duct → urethra → release from body (see also Fig. 50-3). • Testosterone stimulates development of the male's primary and secondary sex characteristics, maintains the secondary sex characteristics, and stimulates spermatogenesis.

• See figure below; also compare to Fig. 50-8.

50.3 • In oogenesis, a primary oocyte gives rise to only one ovum; compare to a primary spermatocyte giving rise to four sperm cells during spermatogenesis. • If the secondary oocyte were fertilized, it could not develop without the hormones produced by a corpus luteum.

See also Fig. 50-15a. FSH stimulates follicle development. Estrogens stimulate the endometrium to thicken; estrogens are necessary for the development of the sex organs at puberty, and for the development and maintenance of female secondary sex characteristics. **50.4** • If a woman becomes pregnant, hCG signals the corpus luteum to continue to function. • Without sufficient estrogen and progesterone, the embryo would be spontaneously aborted. Estrogen is necessary for the development and maintenance of the uterine wall, and progesterone inhibits uterine contractions that might expel the embryo. • High levels of estrogen secreted by the placenta greatly increase the number

of receptors for oxytocin in the uterine wall. As a result, the uterus becomes more responsive to oxytocin, the hormone that stimulates uterine contractions. **50.5** • Muscle tension increases and certain tissues (including tissues in the penis, vagina, and clitoris) become engorged with blood (vasocongestion); heart rate and respiration increase. **50.6** • Hormone methods of contraception inhibit ovulation. • Sterilization would have the greatest impact on the number of unwanted pregnancies; other methods with low failure rates are injectable or implanted hormone contraceptives and IUDs. • A spontaneous abortion, or miscarriage, occurs naturally; a therapeutic abortion is performed when the mother's life is in danger or when there is evidence that the embryo will be grossly abnormal. **50.7** • The two most common STIs in the United States are human papillomavirus (HPV) and *Chlamydia*. • Pelvic inflammatory disease (PID), a serious infection that can lead to infertility, can be caused by chlamydia.

Figure Questions

FIG. 50-8 Without LH, the testes could not produce testosterone; sperm production would stop, his sex drive would decrease, and his secondary sex characteristics would be negatively affected. **FIG. 50-14** When estrogen level is very low, ovulation does not take place and symptoms of menopause may occur. **FIG. 50-15** FSH would continue to be released and new follicles would develop.

Test Your Understanding

1. c 2. e 3. a 4. b 5. e 6. a 7. a 8. e 9. d 10. c

11.

See also Fig. 50-9b. 12. LH and estrogen; mid to late postovulatory phase; estrogen and progesterone. 13. Cross-fertilization increases variability in the offspring, increasing their chance of surviving in a changing environment. 14. Some animals may have mutations that help them resist parasites. Sexual

reproduction allows such beneficial mutations to spread through the population. 15. Sociological factors—historically women have been held responsible for contraception; biological factors—there are more opportunities for intervention in the female. Development of a method of male contraception might focus on reduction of sperm production in the seminiferous tubules, or on methods that would decrease sperm motility or viability. 16. Countries where abortions are legal and safe are most likely higher income countries in which people have easier access to contraception (and can also afford contraception).

Chapter 51

Checkpoint

51.1 • Cell determination generally precedes cell differentiation. • Pattern formation is the process that leads to morphogenesis through the organization of differentiated cells. The steps in pattern formation include cell-to-cell signaling, cell migrations, changes in cell shape, and apoptosis. **51.2** • Species-specific recognition molecules ensure that sperm and egg are of the same species. Events occurring at the time of fertilization ensure that more than one sperm cannot enter the egg (i.e., prevent polyspermy). • Although the details differ, the cortical reaction serves as a block to polyspermy in both echinoderms and mammals.

51.3 •

Also compare your sketches to Figure 30-5. • Meroblastic cleavage (cleavage restricted to the blastodisc). • Large amounts of yolk in the egg cytoplasm tend to slow down cleavage in the embryo. As a consequence, the vegetal pole cells of embryos developing from moderately telolecithal eggs tend to be fewer and larger than the animal pole cells. The yolk of embryos developing from extremely telolecithal eggs does not cleave

at all (meroblastic cleavage in non-avian reptiles and birds). **51.4** • The archenteron is the embryonic forerunner of the digestive tract. It is formed in sea stars and amphibians, but not in birds. • Large amounts of yolk prevent the simple type of gastrulation that occurs in echinoderms and amphioxus. Instead, the establishment of the three embryonic cell layers is accomplished as cells migrate from the cell surface and move into the interior of the embryo. **51.5** • Ectoderm: outer skin layer, nervous system, and sense organs; mesoderm: notochord, skeleton, muscles, circulatory system, reproductive system; and endoderm: lining of digestive tube. Refer to Table 51-1 for a more complete list. • Neural plate cells differentiate in response to inductive signals from the underlying notochord tissue. These cells undergo a process of morphogenesis in which their shapes change, converting the neural plate into the neural tube, which eventually sinks below the surface. The cells of the neural tube subsequently differentiate into specialized cells of the central nervous system. • Neural crest cells are extremely versatile cells that give rise to parts of spinal nerves; they also migrate to various locations in the embryo, giving rise to many structures, including parts of the peripheral nervous system, various sense organs, parts of the head, and pigment-forming cells. **51.6** • Chorion: gas exchange and contributes to placenta in mammals; amnion: protection from desiccation and shocks. • In birds the allantois stores wastes and the yolk sac stores nutrients. In mammals the allantois contributes to the blood vessels in the umbilical cord and blood cells form in the walls of the yolk sac. **51.7** • The human embryo undergoes cleavage while being propelled down the oviduct, developing into a blastocyst (a blastula) after it enters the uterus. Trophoblast cells (the outer cell layer of the blastocyst) secrete enzymes that implant the blastocyst in the uterine wall. • The placenta develops from embryonic tissue (the chorion, which develops from trophoblast cells) and maternal uterine tissue, and serves as the organ of exchange between mother and embryo. • The cerebrum develops lobes at four months; limb buds appear at four weeks. • Rapid changes in the circulatory system are required as the embryo begins to breathe air. Most notably the blood that bypassed the lungs during fetal life becomes redirected to the lungs. In addition, the neonate's digestive system must begin to function because it is no longer supplied by nutrients from the mother.

Figure Questions

FIG. 51-3 Also compare your sketch to Figure 51-3g. The innermost cavity is the archenteron, surrounded by the blastocoel. Your sketch should not include the blastopore.

Answers / **A-81**

FIG. 51-4 Also compare your sketch to Figure 51-4j. It should not include the blastopore.

FIG. 51-5 Also compare your sketch to Figures 51-4d and 30-5b.

FIG. 51-6 Also compare your sketch to Figure 51-3c.

FIG. 51-8 It is unlikely that development would proceed beyond a few divisions because a blastomere lacking a gray crescent would lack cytoplasmic determinants required to support normal development. **FIG. 51-9** Archenteron: gut; blastopore: anus; blastocoel: nothing.

Test Your Understanding

1. b 2. d 3. a 4. d 5. b 6. e 7. b 8. b 9. c 10. b 11. c 12. a 13. The modern view is that eggs and sperm contain genetic instructions that interact with developmental determinants in the egg cytoplasm to direct development. 14. Some teratogenic medications such as thalidomide are of significant medical value, but their use must be carefully regulated to prevent birth defects. 15. A human embryo possesses a notochord, which does not support the adult body as in amphioxus, but is responsible for the induction of the overlying cells to form the neural plate, the forerunner of the dorsal hollow nerve cord, which then develops into the brain and spinal cord. A postanal tail develops, but does not persist (although it is evident in many of our primate relatives). Pharyngeal pouches, pharyngeal grooves, and branchial arches develop in the region of the pharynx. Slits do not form between the pouches and grooves, and they are not used for filter feeding (as in amphioxus) or for respiration (as in fishes). However, they and the branchial arches of supporting tissue give rise to many structures in the head, jaws, and neck (see Section 51.5). These structures have persisted because evolution is conservative and commonly builds upon pre-existing structures. 16. The placenta allows the embryo to develop within the body of the mother, which affords much more protection than an egg. 17. Consult Table 51-3 and the March of

Dimes website for information on environmental influences to be avoided during (and even before) pregnancy. Your challenge as a public health official will be to devise programs that will effectively improve and extend maternal education and care.

Chapter 52

Checkpoint

52.1 • *Philanthus* performs a complex series of behaviors as she provides for her larva. Her behaviors increase the probability that her offspring will survive. The number of viable offspring an animal produces is a measure of its direct fitness. Therefore, the behaviors of *Philanthus* are adaptive. • Sample answer: A child inherits genes for tallness and the capacity to run fast. However, individuals who want to be Olympic athletes must train for many years to improve their basic capacity to run. These athletes must learn how to modify and improve their muscle structure, form, and speed. • Innate behavior occurs when the animal is physiologically ready. Physiological readiness also affects the capacity for learned behavior. For example, a baby cannot learn to walk or play the piano until her body is physiologically ready. **52.2** • Imprinting is adaptive because the young learn to stay close to their mother, increasing their chance of survival. • Operant conditioning is adaptive because animals learn how to obtain food and other necessities; they also learn how to avoid dangerous or unpleasant stimuli. **52.3** • It is adaptive for some species to be diurnal while others are nocturnal or crepuscular because it decreases competition for food and other resources. • Directional orientation refers to travel in a specific direction. In navigation, an animal must integrate information about distance and time, as well as direction. **52.4** • Optimal foraging is the most efficient way for an animal to obtain food. • Optimal foraging is adaptive because the animals maximize their energy intake per unit of foraging time. This approach may maximize their reproductive success. **52.5** • The costs of living in groups include increased competition for food and habitats, increased risk of attracting predators, increased risk of transmitting disease, and time and energy used to gain and maintain social status. The benefits include defense against predators, help in foraging, and opportunities to receive help from others in the group. • Advantages of pheromones include that they are a simple, widespread means of communication, and very little energy is required for their synthesis. They are effective in the dark and can be used to communicate danger, ownership of a territory, and availability for mating. Disadvantages include that they are transmitted slowly and the information that can be conveyed is limited. • The benefits of being dominant in a dominance hierarchy often include greater opportunity to mate and the right to eat first. Limitations include the need to maintain the position, which may require fighting. Subordinate individuals may be protected by the dominant animal, but may not have as much opportunity

to mate or eat. • Benefits of territoriality often include a higher probability of mating and exclusive rights to food within the territory. Costs of territoriality include the time and energy expended in staking out and defending a territory and the risks involved in fighting for it. • Although it is the most sophisticated communication known among nonmammals, the dance of bees is highly stereotyped compared with human language. **52.6** • Sexual selection is a type of natural selection for successful mating. Factors that may influence mate choice include rank in a dominance hierarchy, ornamental displays, physical attributes that indicate good health or strength, and gifts presented to the female. • Polygyny is favored when the male is not needed to feed and protect the young; polyandry is favored when more than one male may help in caring for the young and when the males give gifts to the female. Monogamy is uncommon because it reduces direct fitness. • Benefits of courtship rituals include ensuring that the male is really a male and that he is a member of the same species. Rituals also provide opportunity for a female to evaluate a male. • Females who invest in parenting have more to gain than males because females of many vertebrate species produce relatively few, large eggs. The time and energy invested in producing eggs and carrying the developing embryo make it important for the female to continue to protect her investment. In addition, female mammals provide milk to nourish their young. The benefit is viable offspring and increased direct fitness. For males of most species, the costs of investing in parental care are outweighed by the benefits of mating with multiple females, thus increasing their direct fitness. **52.7** • Kin selection increases inclusive fitness through the breeding success of close relatives. Natural selection favors animals that help a relative (altruistic behavior) because the relative's offspring carries some of the helper's alleles. • An animal may benefit from helping a nonrelative because according to the hypothesis of reciprocal altruism, at some later time the animal will be paid back by the animal it helped. When paid back, the animal that is helped may benefit in terms of safety, obtaining food, or in direct fitness. **52.8** • Vertebrate societies are simpler than insect societies, but they are more flexible. • Examples of culture include female orcas teaching their offspring to hunt seals according to the custom of their particular group and chimps teaching others in their group how to use rocks to crack nuts. • According to sociobiologists, social behavior is determined by natural selection.

Figure Questions

FIG. 52-1 *Philanthus* would be unable to find her nest because she would be prevented from learning the necessary visual cues/landmarks. **FIG. 52-3** The impaired male stickleback would be less likely to father offspring so his direct fitness would decrease. **FIG. 52-6** The boy would likely be scared and would cry because he has become conditioned to associate dogs with pain. **FIG. 52-21** The males would not have reduced their level of guarding the eggs.

Test Your Understanding

1. a 2. b 3. c 4. d 5. b 6. a 7. d 8. e 9. b 10. e 11. a 12. c 13. The young salamanders described preferred eating more distant relatives, which increased the probability that their own relatives would survive to reproduce; this is an example of inclusive fitness. 14. In experiment 1, the parentals guarded the young more closely than the eggs. After the young hatched, the parentals perceived that (despite the sneaker males lurking nearby during the egg stage) they were indeed the parents. The increase in care was based on olfactory cues. In experiment 2, the parentals guarded the eggs more closely than the young. After the young hatched, olfactory cues from the offspring indicated lack of paternity. 15. During times of prey scarcity, the groups with three and four females were most likely to be hungry at the end of the day. Perhaps when there are more animals in the group, they can venture farther in search of prey or take down larger prey. 16. The society of a social insect is more rigid and less flexible than human society. Information about behavior is largely transmitted genetically; like culture, genetic information is passed from parent to offspring. The young share the behavior of the parents. An important difference is that the insect society remains rigid and unlikely to change, whereas the human society is more flexible and more likely to change. 17. Sea turtle migration may be adaptive because it reduces competition between sea turtles of various ages. Young turtles are more likely to find food when they do not need to compete with older turtles. Migration may also be adaptive in that turtles return to the beach where their ancestors hatched. Those ancestors survived the conditions on that beach, suggesting that the new generation of offspring will also be able to survive. 18. It is unlikely that sea turtles could adapt to environmental pressures created by humans over a short period of time. Base your opinion on what you have learned in your biology course.

Chapter 53

Checkpoint

53.1 • Population density is the number of individuals per unit of area or volume. Population dispersion is spacing of individuals relative to one another. • A clumped dispersion can be advantageous to social animals, but it can be disadvantageous if there is competition within the population. **53.2** • Natality (the birth rate) and immigration contribute to population growth; mortality (the death rate) and emigration contribute to population decline. • A J-shaped population growth curve (exponential growth) describes a population at its intrinsic rate of increase ($r_{\max}$). An S-shaped growth curve (logistic growth) describes the decline in a population's growth rate as it approaches its carrying capacity (K), the largest population that can be maintained indefinitely.

Nutrient medium is replenished.

Nutrient medium is not replenished.

Also compare your graphs to Figure 53-2 (bacteria could grow exponentially for a time if the medium is to provide nutrients and waste removal) and Figure 53-3 (bacteria would exhibit logistic growth as they approach their carrying capacity).

53.3 • Three density-dependent factors that influence population growth are predation, disease, and competition. • Density-independent factors include abiotic events such as extreme weather, fires, and floods. **53.4** • In semelparity an organism puts all of its resources into a single reproductive event. These resources tend to improve the chances of success, but all is lost if the effort fails. Iteroparity provides many chances for reproduction; however, the organism's reproductive resources may become depleted by repeated reproductive cycles. • Parental care improves survival of the young when the population is at or near its carrying capacity. • Survivorship curves do not neatly fit the three models: Type I, Type II, and Type III. For example, a species' survivorship curve can be different early in life compared to later in life. **53.5** • In a metapopulation, excess individuals tend to move from good or source habitats, where population growth is greatest, to less favorable sink habitats where population success is poorer. **53.6** • The dramatic increase in the world population over the last 200 years is attributable to a dramatic decrease in the death rate. • Replacement-level fertility is higher in developing countries because they have higher infant mortality rates than do developed countries. • Unlike a child born in a developing country, a single child born in the United States is a major contributor to consumption overpopulation.

Figure Question

FIG. 53-6 As is often the case in science, you will need more information to develop your hypothesis. You will want to gather information on such abiotic factors as changes in climate and

specific weather events. You will also need information on biotic factors such as organisms other than spiders and lizards (including microorganisms) that may be living within the enclosures and affecting the spider populations.

Test Your Understanding

1. b 2. b 3. c 4. b 5. a 6. d 7. e 8. a 9. b 10. e 11. c 12. b 13. The pattern of repeated reproduction exhibited by female elephants is characteristic of Type I survivorship, in which individuals of reproductive age have a high probability of surviving. 14. Interference competition, in which a few individuals obtain adequate resources and others do not, is more sustainable than exploitation competition, which can lead to population booms (exceeding the carrying capacity) and crashes. 15. A population that can be described as *r*-selected is mainly characterized by overproduction of offspring and is kept in check by limits on population growth. A *K*-selected population is more stable; reproductive success is achieved with production of fewer offspring who are more likely to survive and reproduce. 16. Bolivia, with a much higher percentage of its population entering reproductive age, has greater population growth momentum than Austria, and can be expected to have a higher growth rate over the next two decades. 17. With about 1084 people per square mile, the population density of the Netherlands is much greater than that of the United States (about 88 per square mile). 18. 1,371.5 million. 19. 8 per 1000. 20. The diagram depicting population (b), with a very small proportion of its population at reproductive age or prereproductive age is consistent with negative population growth momentum. 21. A few examples of technologies that contribute to consumption overpopulation are those that typically involve the exploitation of fossil fuels (electricity, planes, trains, motor vehicles), rare elements (electronics), and those that produce pollution as a byproduct. New technologies to address some of these problems are being developed all the time. Which ones do you think might be most promising?

Chapter 54

Checkpoint

54.1 • Abundant acorn crops attract mice to oak forests. Mice eat the acorns, so more mice survive and breed in winter. Gypsy moths cause serious damage to oak trees, but mice also eat gypsy moth pupae, reducing their numbers. Both deer and mice are hosts to ticks. The mice often carry the bacteria that cause Lyme disease. The bacteria infect the ticks and are spread to humans when they are bitten by infected ticks. • The realized niche is usually narrower because factors, such as competition with other species, may exclude an organism from a part of its fundamental niche. • The principle of community ecology illustrated by the example is resource partitioning. • The three

kinds of symbiosis are mutualism, commensalism, and parasitism. Refer to the section “Symbiosis involves a close association between species” for examples of each. 54.2 • Dominant species are present in great abundance in a community, while keystone species are present in low abundance. • Reintroduced wolves would reduce the herbivore population (such as deer and elk) which, in turn, would allow more and varied plant species to grow. It is an example of a top-down process because the predators (wolves) impact the abundance of herbivores and producers in the community. 54.3 • Species richness is reduced by geographic isolation due to the distance effect, where species are unable to colonize islands due to distance; species richness can also be reduced by random events in mountain or island habitats, which cause species extinction. Locally extinct species are not readily replaced in these isolated habitats. • The structural complexity of habitats such as forests and coral reefs can enhance species richness because they provide numerous diverse ecological niches. New species may migrate to these areas; and over time, new species may evolve there. • Species richness is inversely related to the environmental stress of a habitat because only species that can tolerate the particular type of environmental stress survive, while species that are unable to adapt to the environmental stress become extinct. 54.4 • Primary succession is the change in species composition over time in a habitat without soil that was not previously inhabited by organisms; secondary succession is the change in species composition that takes place after some disturbance removes the existing vegetation from a habitat containing soil. • Connell’s intermediate disturbance hypothesis proposes that species richness is greatest at moderate levels of disturbance where the community is a mosaic of habitats at different stages of succession. • Organismic models of the nature of communities propose that member species cooperate with one another in a manner similar to the cooperation of the parts of an individual organism’s body. The community passes through stages of development, like the embryonic stages of an organism, eventually reaching an adult state, or climax community. Individualistic models of the nature of communities propose species individuality, with each species having its own particular abiotic living requirements; communities are not interdependent associations of organisms, and each species is independently distributed across a continuum of areas that meets its own individual requirements.

Figure Questions

FIG. 54-5 *P. caudatum* would show increase in population density similar to the second graph, while *P. aurelia* would decrease in population density. FIG. 54-7 If the *G. fuliginosa* population were removed from the shared island, the smaller seeds it ate would become more available to *G. fortis*. Over time, a smaller bill depth might evolve in the *G. fortis* population, adapting these finches to the wider seed selection. FIG. 54-18 A species richness graph compiled from a tundra habitat would likely

have fewer bird species because the community would have a lower structural complexity of vegetation. FIG. 54-19 About 60% of species have colonized islands at 2000 km and about 20% have colonized islands at 6000 km. The greater the geographic isolation, the lower the species richness. FIG. 54-20 A gradual increase in temperature could result in an increase in species richness as more bird species move into a warmer, more favorable habitat.

FIG. 54-23

Palm tree: The curve on the graph would begin at a high number on the y-axis at the wet end of the x-axis; the slope would decrease down to the dry end of the x-axis. Cactus: The curve for the cactus would begin at a low number on the y-axis at the wet end of the x-axis; the slope would increase as the line approaches the dry side of the x-axis.

Test Your Understanding

1. e 2. c 3. d 4. e 5. c 6. d 7. b 8. a 9. d 10. d 11. e 12. d 13. Humans are a keystone species as we determine the species composition and functioning of our ecosystem, for better or to our detriment. 14. Plants containing nitrogen-fixing nodules can provide nitrogen in the surrounding soil for other plants to grow but may grow better and faster, excluding other plant species. 15. Natural selection has tipped the predator-prey balance in favor of the garter snake populations that tolerated newt toxin. Over time, newt populations may develop (through natural selection) a new defense strategy that would deter the garter snake. The predator-prey balance changes. 16. Competition among finch populations drives natural selection. Character displacement and resource partitioning both reduce interspecific competition, increasing the overall fitness of the different species. 17. The top and middle graph show logistic population growth. The K, or carrying capacity, for the two *Paramecium* growth curves occurs at a point where there is no further increase in population and is indicated by a flat line. 18. The human ecological niche constantly changes and expands as we learn about our surroundings and adapt to the challenges of survival. Science and technology provide us with

the means to understand and thrive in our ecological niche. Failure of society to promote an understanding of science and misuse of technology could cause our ecological niche to shrink and endanger our survival. (Answers will vary as to how science and technology have changed our ecological niche over the past 1000 years.)

Chapter 55

Checkpoint

55.1 • See figure below; also compare to Fig. 55-2.

• A trophic level is each sequential level of matter and energy in a food web, from producers to primary, to secondary, to tertiary consumers; each organism is assigned to a trophic level based on its primary source of nourishment. Ecological pyramids illustrate how food webs work and where members of each trophic level fit. • Gross primary productivity is a measurement of the rate at which energy accumulates in an ecosystem during photosynthesis, while net primary productivity is the energy that remains after plant cellular respiration has occurred. Gross primary productivity minus plant cellular respiration is net primary productivity. 55.2 • During photosynthesis, CO₂ in the air is fixed by plants and some prokaryotes; cellular respiration, combustion, and erosion return CO₂ to the atmosphere.

See also Fig. 55-8. • Phosphorus cycles from land and terrestrial organisms to ocean and marine organisms and back to land and terrestrial organisms. 55.3 • The circulation of the atmosphere is primarily driven by the energy from the sun; different temperatures at different locations cause warm air to rise and cooler air to sink, creating movement. Earth's rotation and ocean currents also play a role in atmospheric circulation. • Ocean currents are produced by persistent prevailing winds blowing over the ocean surface; the Coriolis effect causes currents to swerve right in the Northern Hemisphere and left in the Southern Hemisphere. • Factors that produce regional differences in precipitation are wind movement over air and water; landmass features such as mountains, valleys, and deserts; ocean water temperatures; currents; and upwelling. 55.4 • The deforestation study observed that when a forest is removed, the total amount of water and minerals that flow into streams increases drastically. Also, deforestation causes soil erosion and leaching of essential minerals, resulting in decreased soil fertility.

Figure Questions

FIG. 55-1 Once the sun ceased to provide light for plant growth, all the organisms would starve. The decomposers would be left to consume the remains before eventually dying themselves.

FIG. 55-2 Plants would produce less and gradually die, leaving many insects and small animals without enough food or shelter. Larger animals would leave as smaller animals disappeared or flew away. Decomposers would consume remains. What was left of the dry, weakened forest would be more susceptible to fire.

FIG. 55-6 The gulls might be consumed by larger birds, which could eventually die from the high bioaccumulation of DDT. When the gulls die, decomposers could be poisoned by consuming the remains. The DDT would not disappear from the salt marsh ecosystem. **FIG. 55-15** Increases in land temperature could cause wind speeds to increase, which would produce stronger currents, causing greater upwelling and dead zones. Water temperature increase would alter density of water near the shore, causing fresh water to flow into oceans and change surface current patterns.

Test Your Understanding

1. d 2. e 3. a 4. d 5. e 6. a 7. b 8. c 9. d 10. d 11. b

See also Fig. 55-1. 13. If all decomposers were eliminated from a food web, organic material from waste and remains would not be broken down to simple inorganic compounds. All other life would eventually cease to exist as inorganic compounds became depleted. 14. The cycling of matter is essential because life requires accessible building materials for long-term continuance; materials must be reused and recycled within and among ecosystems. 15. The nitrogen cycle would collapse if bacteria were absent because the five steps bacteria perform (nitrogen fixation, nitrification, assimilation, ammonification, and denitrification) are all essential to the cycle. 16. The microclimate for the ant and for the elephant would be different. The ant inhabits a microclimate close to the ground, in moist air and under shade from trees. The elephant's microclimate is a drier atmosphere, surrounded by sunlight and wind. 17. The pyramid is inverted because the plankton (microscopic algae and animals) are highly productive and experience high rates of turnover (are short lived and reproduce rapidly). 18. The graph indicates that wildfires increase as temperatures increase. Climate warming may be causing more wildfires because the second half of the graph (1985–2005) indicates higher temperatures and more fires; more data for a longer period of time may support this observation. 19. Humans alter the nitrogen cycle through overuse of nitrogen fertilizer, raw sewage dumping, and automobile/power plant/factory emissions. Scientists can partner with educators to explain the problem to the public while working with engineers to develop methods to mitigate the current damage and prevent future problems. The public can, in turn, encourage legislators to enact laws and set money aside for reducing nitrogen pollution and for education.

Chapter 56

Checkpoint

56.1 • Tundra: long, cold winters and short summers, little precipitation; geologically young soil with permanent layer of permafrost. Boreal forest: cold winters and short growing

season; acidic, mineral-poor soil. Temperate rainforest: cool weather, dense fog, high precipitation; nutrient-poor soil, which may have high organic content. Temperate deciduous forest: hot summers and cold winters, high precipitation; soils rich in organic matter at surface and deeper clay layer. Temperate grasslands: hot summers and cold winters, moderate to unpredictable precipitation; soils rich in organic matter; roots/rhizomes. Chaparral: mild, wet winters and hot, dry summers; thin and infertile soil. Deserts: cold or warm temperatures, very low precipitation, and soil low in organic material, but high in mineral content. Savanna: tropical temperatures, low rainfall with dry periods; soil low in essential minerals, may be high in aluminum. Tropical dry forests: wet season and dry season, high precipitation; soil with some organic matter but low in essential minerals. Tropical rain forest: tropical temperatures, high year-round precipitation; old, highly weathered, mineral-poor soil with low organic content. • Boreal forest: caribou, wolves, bears, moose, rodents, lynx, seasonal birds, and few reptiles and amphibians. Temperate deciduous forest: mountain lions, wolves, bison, deer, many small animals, insects, birds, reptiles, and amphibians. Temperate rain forest: mule deer, elk, small rodents, insects, many birds, some reptiles and amphibians. Tropical rain forest: greatest number and diversity of insects, bird, reptiles, and amphibians; sloths, monkeys, elephants. • Answers will vary. • Tundra is generally cold and dry, while deserts may be cold or hot as well as dry. Animals and plants in both tundra and desert are adapted to extreme temperatures and limited water. Temperate grassland has cold winters and more rainfall, while savanna is warm year round and has low rainfall and dry periods. Animals and plants are abundant; drought, fire, and overgrazing are significant in both biomes. **56.2** • If ocean plankton disappeared, plankton-eating nekton would lose their food source and die off. Carnivorous nekton (sharks, whales) would lose much of their food source and die. Benthos would, in turn, lose most of their food sources that float down from the surface, and their population would be decimated as well. The ocean would rapidly lose most living organisms. • Salinity, dissolved oxygen, light availability, water depth, essential minerals,

temperature, pH, and presence/absence of waves and currents are environmental factors that determine the adaptations of organisms that live in aquatic environments. • Freshwater wetlands are covered part of the year by shallow water, while estuaries are coastal areas near rivers where fresh water mixes with tidal salt water. In flowing-water ecosystems, there is a flowing current; in standing-water ecosystems, the top layer, due to light penetration, contains phytoplankton, zooplankton, and fishes, while the lower, dark zone contains mostly prokaryotic decomposers. • The intertidal zone, shoreline area between low tide and high tide, has organisms with adaptations that resist wave action and exposure to air during low tide. The benthic environment, the ocean floor, has sea grasses, kelps, and coral reefs in shallow ocean waters. The neritic province is open ocean from shoreline to 200 m. Organisms are all floaters or swimmers. The euphotic zone, the upper part of the neritic province, has phytoplankton that are the base of the food web. The oceanic province is the part of the open ocean deeper than 200 m. It is dark, cold, and has a high pressure. Animals are either predators or scavengers that subsist on marine snow. • Coral reefs are often compared to tropical rain forests because of their immense diversity of life and high productivity. **56.3** • An ecotone is the transition area where two communities, or biomes, meet and intergrade. Ecotones occur where agricultural land meets forest, tundra borders a boreal forest, or a river touches land. **56.4** • Biogeography is the study of the geographic distribution of plants and animals. Biogeographers look for patterns in geographic distribution and try to explain how such patterns arose, including where populations originated, how they spread, and when. • The Australian realm has been separated from the other biogeographic realms for the longest period; animals living in the Australian realm include marsupials and monotremes, such as the kangaroo, platypus, and spiny anteater.

Figure Questions

FIG. 56-1 As climate changes, plants, animals, and other organisms will disappear if they are unable to adapt. They may be replaced or outcompeted by species that can adapt more rapidly to these climate changes. **FIG. 56-24** Fireweed and knotweed have adapted to the serpentine soil and would have too much competition to colonize the ecotone area.

Test Your Understanding

1. c 2. a 3. d 4. e 5. c 6. b 7. d 8. a 9. c 10. e 11. e 12. Desert animals may be small because they have limited food and water resources. To test this hypothesis, a desert animal experimental group could be provided with abundant amounts of food and water for numerous generations. 13. The lowest average annual precipitation characteristic of tropical rain forests is 225 cm. The highest average annual precipitation is 450 cm. The range of average temperature in tropical rain forests is

20°C – 28°C. 14. Eight sampled species are found in the non-serpentine soil. Ten sampled species are found in the serpentine soil. Thirteen are found in the ecotone. The ecotone supports more plant species than serpentine or nonserpentine areas alone. 15. Organisms adapted to a fast current would be displaced by organisms that thrive in still water. Upstream organisms' habitats would probably have still water and flooding close to the dam, while downstream organisms' habitats would now have still water and less water. 16. Prairie dogs may bury the dead animal to keep predators from smelling it as a food source and approaching the hole. Researchers could prevent prairie dogs in an experimental group from burying dead animals; the dead animals could be protected in a cage that would allow odors to escape. Prairie dogs in a control group would be permitted to bury dead animals. 17. Technologies employed for data collection could be coastal and ocean buoys, satellite pictures (visual and IR), and research vessels. Local communities could receive instruction from science educators to count turtle eggs and record breeding data to assist with the research.

Chapter 57

Checkpoint

57.1 • The three levels of biological diversity are genetic diversity, species richness, and ecosystem diversity. • An endangered species would be at greater immediate risk of extinction because there are fewer surviving members of the species throughout its range compared with a threatened species. • Habitat fragmentation contributes to declining biological diversity because it encourages disease organisms, as well as invasive species that compete with native species. • Invasive species contribute to the biodiversity crisis because they cause more damage to native species than do native competitors or predators. Native species are not usually evolutionarily equipped to deal with invasive species. **57.2** • If conservation biology did not exist, many species would not be protected and could become extinct; biodiversity would plummet. • Landscape biology and restoration ecology are examples of in situ conservation. • In situ conservation helps the greatest number of species because it keeps the ecosystems intact and maintains biodiversity on a large scale. • The U.S. Endangered Species Act is controversial because it pits landowners against conservationists, in most cases without developing effective means of fostering education and cooperation between the groups. It is also a very slow, political, litigious process to list species. **57.3** • Three ecosystem services that forests provide are wildlife habitat, protection of watersheds, and prevention of soil erosion and flooding. • Deforestation in tropical rain forests is caused by subsistence agriculture and slash-and-burn agriculture. The main reason for deforestation of boreal forests is clear-cut logging. **57.4** • The enhanced greenhouse effect involves increased

levels of greenhouse gases that absorb infrared (heat) radiation, combined with additional warming of the atmosphere. The enhanced greenhouse effect is caused by human actions, such as industrialization without mitigation of pollutants. • Climate change may cause oceans to rise, ice caps and glaciers to melt and disappear, increased water and atmospheric temperatures, reduction of species and diversity, higher frequency and more intense storm systems and wildfires, and increased disease.

Figure Questions

FIG. 57-2 The oystercatcher population would experience changes in genetic diversity if it interbreeds with the newcomer population or could be reduced or eliminated if competition became extreme. **FIG. 57-4** Effectively addressing social, political, and cultural factors, for example by education, could result in greater societal commitment to addressing and changing the direct effects of declining biodiversity, such as pollution and climate change. **FIG. 57-6** Bay scallop populations will decrease, and the species may no longer be able to survive in that habitat. **FIG. 57-9** A large human population could insulate and protect the endemic species through education, research, and well-planned land use solutions. **FIG. 57-17** Accumulation of greenhouse gases can be slowed by humans changing their lifestyles, such as reducing carbon footprint, purchasing low emission energy and automobiles, and maximizing recycling opportunities.

Test Your Understanding

1. d 2. e 3. c 4. c 5. c 6. b 7. e 8. d 9. c 10. a 11. Captive breeding may fail because reintroduced species may no longer be able to compete in their original habitats. 12. Human decisions, good and bad, ultimately affect the outcome of survival of organisms and protection of our planet. 13. Modern humans are the most dangerous species, to ourselves and other inhabitants of Earth. 14. Any loss of species is permanent, and every genetic code and genome could potentially be of future benefit for medicine, research, or other economic interests. 15. Multiple introductions, each under slightly different circumstances (weather, predators, nutrient level), could give some of the invasives the edge to thrive. 16. The production of many smaller eggs could be due to more protected surroundings and nourishment not afforded to eggs in the wild, which would need to be bigger and heartier. Captive-bred females might have lower survival rates than wild females. 17. Habitat fragmentation is most important. Climate change and increasing atmospheric CO₂ are represented as separate factors because they have multiple causes. Nitrogen pollution relates to overuse of fertilizer and nitrogen-containing emissions that cause air pollution. 18. Education and dialogue between the public, scientists, and developers of technology in all countries would be essential to developing and implementing a plan for all residents of Earth that would be sustainable for developed (high income) and developing (lower income) countries.

Glossary

ABC transporters ATP-binding cassette transporters; use ATP energy to transport certain ions, sugars, and polypeptides across cell membranes.

abiotic factors Elements of the nonliving, physical environment that affect a particular organism. Compare with *biotic factors*.

abortion Termination of pregnancy, resulting in the death of the embryo or fetus; abortions can occur spontaneously or can be induced.

abscisic acid (ABA) (ab-sis'-ik) A plant hormone involved in dormancy and responses to stress.

abscission (ab-sizh'-en) The normal (usually seasonal) fall of leaves or other plant parts, such as fruits or flowers.

abscission zone The area at the base of the petiole where the leaf will break away from the stem. Also known as the *abscission layer*.

absorption (ab-sorp'-shun) (1) The movement of nutrients and other substances through the wall of the digestive tract and into the blood or lymph. (2) The process by which chlorophyll takes up light for photosynthesis.

absorption spectrum A graph of the amount of light at specific wavelengths that is absorbed as light passes through a substance. Each type of molecule has a characteristic absorption spectrum. Compare with *action spectrum*.

abyssal zone Part of benthic environment that extends from a depth of 4000 to 6000 m.

acanthodians (ak-an-tho'-de-uns) An extinct group of armored jawed fishes; possessed paired spines and pectoral and pelvic fins.

accessory fruit A fruit consisting primarily of tissue other than ovary tissue (e.g., apple, pear). Compare with *aggregate, simple, and multiple fruits*.

acclimatization Adjustment to seasonal changes.

acetyl coenzyme A (acetyl CoA) (as'-uh-teel) A key intermediate compound in metabolism; consists of a 2-carbon acetyl group covalently bonded to coenzyme A.

acetylcholine (ah'-see-til-koh'-leen) A common neurotransmitter released by cholinergic neurons, including motor neurons.

acetyl group A 2-carbon group derived from acetic acid (acetate).

achene (a-keen') A simple, dry fruit with one seed in which the fruit wall is separate from the seed coat (e.g., sunflower fruit).

acid A substance that is a hydrogen ion (proton) donor; acids unite with bases to form salts. Compare with *base*.

acidic solution A solution in which the concentration of hydrogen ions $[H^+]$ exceeds the concentration of hydroxide ions $[OH^-]$. An acidic solution has a pH less than 7. Compare with *basic solution* and *neutral solution*.

acid precipitation Precipitation that is acidic as a result of both sulfur and nitrogen oxides forming acids when they react with water in the atmosphere.

acoelomate (a-seel'-oh-mate) An animal lacking a body cavity (coelom). Compare with *coelomate* and *pseudocoelomate*.

acquired immune responses See *adaptive immune responses*.

acquired immunodeficiency syndrome (AIDS) A serious, potentially fatal disease caused by the human immunodeficiency virus (HIV).

acromegaly (ak'-roh-meg'-ah-lee) A condition characterized by overgrowth of the extremities of the skeleton, fingers, toes, jaws, and nose. It may be produced by excessive secretion of growth hormone by the anterior pituitary gland.

acrosome reaction (ak'-roh-sohm) A series of events in which the acrosome, a caplike structure covering the head of a sperm cell, releases proteolytic (protein-digesting) enzymes and undergoes other changes that permit the sperm to penetrate the outer covering of the egg.

actin (ak'-tin) The protein of which microfilaments consist. Actin, together with the protein myosin, is responsible for muscle contraction.

actin filaments Thin filaments consisting mainly of the protein actin; actin and myosin filaments make up the myofibrils of muscle fibers.

actinopods (ak-tin'-o-podz) Protists characterized by axopods that protrude through pores in their shells. See *rhizarians*.

action potential An electrical signal resulting from depolarization of the plasma membrane in a neuron or muscle cell. Compare with *resting potential*.

action spectrum A graph of the effectiveness of light at specific wavelengths in promoting a light-requiring reaction. Compare with *absorption spectrum*.

activation energy (E_A) The kinetic energy required to initiate a chemical reaction.

activator protein A positive regulatory protein that stimulates transcription when bound to DNA. Compare with *repressor protein*.

active immunity Immunity that develops as a result of exposure to antigens; it can occur naturally after recovery from a disease or can be artificially induced by immunization with a vaccine. Compare with *passive immunity*.

active site A specific region of an enzyme (generally near the surface) that accepts one or more substrates and catalyzes a chemical reaction. Compare with *allosteric site*.

active transport Transport of a substance across a membrane that does not rely on the potential energy of a concentration gradient for the substance being transported and therefore requires an additional energy source (often ATP); includes carrier-mediated active transport, endocytosis, and exocytosis. Compare with *diffusion* and *facilitated diffusion*.

adaptation (1) An evolutionary modification that improves an organism's chances of survival and reproductive success. (2) A decline in the response of a receptor subjected to repeated or prolonged stimulation.

adaptive immune responses Defense mechanisms that target specific macromolecules associated with a pathogen. Includes cell-mediated immunity and antibody-mediated immunity. Also known as *acquired immune responses* or *specific immune responses*. Compare with *innate immune responses*.

adaptive immunity See *adaptive immune responses*.

adaptive radiation The evolution of a large number of related species from an unspecialized ancestral organism.

adaptive zone A new ecological opportunity that was not exploited by an ancestral organism; used by evolutionary biologists to explain the ecological paths along which different taxa evolve.

addiction Physical dependence on a drug, generally based on physiological changes that take place in response to the drug; when the drug is withheld, the addict may suffer characteristic withdrawal symptoms.

Addison's disease Caused by insufficient secretion of aldosterone and cortisol by the adrenal cortex and characterized by progressive anemia, low blood pressure, and inability to respond to stress.

adenine (ad'-eh-need) A nitrogenous purine base that is a component of nucleic acids and ATP.

adenosine diphosphate (ADP) See *adenosine triphosphate (ATP)*.

adenosine triphosphate (ATP) (a-den'-oh-seen) An organic compound containing adenine, ribose, and three phosphate groups; hydrolysis of the terminal phosphate yields adenosine diphosphate (ADP); of prime importance for energy transfers in cells.

adenyl cyclase Enzyme responsible for catalyzing the conversion of ATP to cyclic AMP (cAMP).

adhering junction A type of anchoring junction between cells; connects epithelial cells.

adhesion The property of sticking to some other substance. Compare with *cohesion*.

adipose tissue (ad'-i-pohs) Tissue in which fat is stored.

adrenal cortex (ah-dree'-nul kor'-teks) The outer region of each adrenal gland; secretes steroid hormones, including mineralocorticoids and glucocorticoids.

adrenal glands (ah-dree'-nul) Paired endocrine glands, one located just superior to each kidney; secrete hormones that help regulate metabolism and help the body cope with stress.

adrenal medulla (ah-dree'-nul meh-dull'-uh) The inner region of each adrenal gland; secretes epinephrine and norepinephrine.

adrenergic neuron (ad-ren'-er'-jik) A neuron that releases norepinephrine or epinephrine as a neurotransmitter. Compare with *cholinergic neuron*.

adrenocorticotrophic hormone (ACTH) Hormone secreted by anterior pituitary that regulates glucocorticoid and aldosterone secretion.

adult stem cells Cells derived from body tissues that can differentiate into some specific cell types (e.g., blood cells, neuronal cells, or muscle cells), but not all types of cells found in an organism. See *pluripotent stem cells* and *totipotent stem cells*.

adventitious (ad'-ven-tish'-us) Of plant organs, such as roots or buds, that arise in an unusual position on a plant.

aerobe Organism that grows or metabolizes only in the presence of molecular oxygen. Compare with *anaerobe*.

aerobic (air-oh'-bik) Growing or metabolizing only in the presence of molecular oxygen. Compare with *anaerobic*.

aerobic cellular respiration See *respiration*.

aerobic respiration See *respiration*.

afferent (af'-fer-ent) Leading toward some point of reference. Compare with *efferent*.

afferent arteriole In the mammalian kidney, an arteriole that conducts blood into the capillaries that make up a glomerulus; afferent arterioles branch from the renal artery. Compare with *efferent arteriole*.

afferent neurons Neurons that transmit action potentials from sensory receptors to the brain or spinal cord. Compare with *efferent neurons*.

age structure The number and proportion of people at each age in a population. Age structure diagrams represent the number of males and females at each age, from birth to death, in the population.

age structure diagram See *age structure*.

aggregated distribution See *clumped dispersion*.

aggregate fruit A fruit that develops from a single flower with many separate carpels (e.g., raspberry). Compare with *simple*, *accessory*, and *multiple fruits*.

aging Progressive changes in development in an adult organism.

agnathans (ag-na'-thanz) Jawless fishes; term is mainly used to refer to the earliest vertebrates, which are now extinct.

AIDS See *acquired immunodeficiency syndrome*.

albinism (al'-bih-niz-em) A hereditary inability to form melanin pigment, resulting in light coloration.

albumin (al-bew'-min) A class of protein found in most animal tissues; a fraction of plasma proteins.

aldehyde An organic molecule containing a carbonyl group bonded to at least one hydrogen atom. Compare with *ketone*.

aldosterone (al-dos'-tur-ohn) A steroid hormone produced by the vertebrate adrenal cortex; stimulates sodium reabsorption. See *mineralocorticoids*.

algae (al'-gee) (sing., *alga*) An informal group of unicellular, or simple multicellular, photosynthetic protists that are important producers in aquatic ecosystems.

allantois (a-lan'-toe-iss) An extraembryonic membrane of reptiles, birds, and mammals that stores the embryo's nitrogenous wastes; most of the allantois is detached at hatching or birth.

allele frequency The proportion of a specific allele in the population. Compare with *genotype frequency* and *phenotype frequency*.

alleles (al-leelz') Genes governing variation of the same character that occupy corresponding positions (loci) on homologous chromosomes; alternative forms of a gene.

allelopathy (uh-leel'-uh-path''-ee) An adaptation in which toxic substances secreted by roots or shed leaves inhibit the establishment of competing plants nearby.

allergen A substance that stimulates an allergic reaction.

allergy A hypersensitivity to some substance in the environment, manifested as hay fever, skin rash, asthma, food allergies, etc.

allometric growth Variation in the relative rates of growth for different parts of the body during development.

allopatric speciation (al-oh-pa'-trik) Speciation that occurs when one population becomes geographically separated from the rest of the species and subsequently evolves. Compare with *sympatric speciation*.

allopolyploid (al'-oh-pol'-ee-ploid) A polyploid whose chromosomes are derived from two species. Compare with *autopolyploid*.

all-or-none response The principle that no variation exists in the strength of a single action potential; only a stimulus strong enough to depolarize the membrane to its critical threshold level results in transmission of an action potential.

allosteric regulators Substances that affect protein function by binding to allosteric sites.

allosteric site (al-oh-steer'-ik) A site on an enzyme other than the active site, to which a specific substance binds, thereby changing the shape and activity of the enzyme. Compare with *active site*.

alpha (α) carbon Asymmetrical carbon in an amino acid to which an amino group, a carboxyl group, a side chain (*R* group), and a hydrogen are covalently bonded.

alpha cells Pancreatic cells that secrete glucagon.

alpha (α) helix A regular, coiled type of secondary structure of a polypeptide chain, maintained by hydrogen bonds. Compare with *beta (β)-pleated sheet*.

alpine tundra An ecosystem located in the higher elevations of mountains, above the tree line and below the snow line. Compare with *tundra*.

alternation of generations A type of life cycle characteristic of plants and a few algae and fungi in which they spend part of their life in a multicellular *n* gametophyte stage and part in a multicellular *2n* sporophyte stage.

alternative splicing A genetic mechanism in which exons are spliced in different ways to produce different mRNAs from a single gene.

altruism A type of cooperative behavior in which an individual appears to behave in a way that benefits another rather than itself.

altruistic behavior Behavior in which one individual helps another, seemingly at its own risk or expense.

alveolates Protists that have alveoli, flattened vesicles located just inside the plasma membrane; include the dinoflagellates, apicomplexans, and ciliates. See *chromalveolates*; compare with *stramenopiles*.

alveolus (al-vee'-o-lus) (pl., *alveoli*) (1) An air sac of the lung through which gas exchange with the blood takes place. (2) Saclike unit of some glands (e.g., mammary glands). (3) One of several flattened vesicles located just inside the plasma membrane in alveolate protists.

Alzheimer's disease (AD) A progressive, degenerative brain disorder characterized by amyloid plaques and neurofibrillary tangles.

amacrine cell A lateral interneuron in the retina of the eye; receives signals from bipolar cells and sends signals back to them or to ganglion cells.

amino acid (uh-mee'-no) An organic compound containing an amino group ($-\text{NH}_2$) and a carboxyl group ($-\text{COOH}$); may be joined by peptide bonds to form a polypeptide chain.

amino acid derivatives Simplest hormones, such as epinephrine and melatonin, that are derived from amino acids.

aminoacyl-tRNA (uh-mee''-no-ace'-seel) Molecule consisting of an amino acid covalently linked to a transfer RNA.

aminoacyl-tRNA synthetase One of a family of enzymes, each responsible for covalently linking an amino acid to its specific transfer RNA.

amino group A weakly basic functional group; abbreviated $-\text{NH}_2$.

ammonification (uh-moe''-nuh-fah-kay'-shun) The conversion of nitrogen-containing organic compounds to ammonia (NH_3) by certain soil bacteria (ammonifying bacteria); part of the nitrogen cycle.

amniocentesis (am''-nee-oh-sen-tee'-sis) Sampling of the amniotic fluid surrounding a fetus to obtain information about its development and genetic makeup. Compare with *chorionic villus sampling*.

amnion (am'-nee-on) In terrestrial vertebrates, an extraembryonic membrane that forms a fluid-filled sac for the protection of the developing embryo.

amniotes Terrestrial vertebrates: reptiles, birds, and mammals; animals whose embryos are enclosed by an amnion.

amniotic egg Egg that contains an amnion and other membranes that surround and protect the developing embryo and keep it moist; the evolution of the amniotic egg was one of the adaptations that allowed animals to become completely terrestrial.

amoeba (a-mee'-ba) (pl., *amoebas*) A unicellular protist that moves by means of pseudopodia.

amoebozoa Members of the unikont clade characterized by lobose pseudopodia at some time in the life cycle; include amoebas, plasmodial slime molds, and cellular slime molds. Compare with *opisthokonts*.

amphibians Members of the vertebrate class that includes salamanders, frogs, and caecilians.

amphipathic lipid See *amphipathic molecule*.

amphipathic molecule (am''-fih-pa'-thik) A molecule containing both hydrophobic and hydrophilic regions.

ampulla Any small, saclike extension (e.g., the expanded structure at the end of each semicircular canal of the ear).

amygdala Part of the limbic system; filters incoming information and interprets it in the context of emotional needs and survival.

amylase (am'-uh-laze) Starch-digesting enzyme (e.g., human salivary amylase or pancreatic amylase).

amyloid plaques Extracellular deposits in the brain containing the peptide amyloid-beta surrounded by degenerating dendrites and axons.

amyloplasts See *leukoplasts*.

anabolic hormone Hormone that promotes tissue growth.

anabolic steroids Synthetic androgens that increase muscle mass, physical strength, endurance, and aggressiveness but cause serious side effects; these drugs are often abused.

anabolism (an-ab'-oh-lizm) The aspect of metabolism in which simpler substances are combined to form more complex substances, resulting in the storage of energy, the production of new cell materials, and growth. Compare with *catabolism*.

anaerobe Organism that can grow or metabolize in the absence of molecular oxygen. See *facultative anaerobe* and *obligate anaerobe*. Compare with *aerobe*.

anaerobic (an'-air-oh'-bik) Growing or metabolizing in the absence of molecular oxygen. Compare with *aerobic*.

anaerobic respiration See *respiration*.

anaphase (an'uh-faze) Stage of mitosis in which the chromosomes move to opposite poles of the cell; anaphase occurs after metaphase and before telophase.

anaphase I See *meiosis* and *meiosis I*.

anaphase II See *meiosis* and *meiosis II*.

anaphase-promoting complex (APC) Enzyme complex responsible for initiating the transition from metaphase to anaphase.

anaphylaxis (an'-uh-fih-lak'-sis) An acute allergic reaction following sensitization to a foreign substance or other substance.

ancestral characters See *shared ancestral characters*.

androgen (an'-dro-jen) Any substance that has masculinizing properties, such as a sex hormone. See *testosterone*.

androgen-binding protein (ABP) A protein produced by Sertoli cells in the testes; binds and concentrates testosterone.

anemia (uh-nee'-mee-uh) A deficiency of hemoglobin or red blood cells.

aneuploidy (an'-you-ploy-dee) Any chromosomal aberration in which there are either extra or missing copies of certain chromosomes.

angiosperms (an'-jee-oh-spermz") The traditional name for flowering plants, a very large (more than 300,000 species), diverse phylum of plants that form flowers for sexual reproduction and produce seeds enclosed in fruits; include monocots and eudicots.

angiotensin I (an-jee-o-ten'-sin) A polypeptide produced by the action of renin on the plasma protein angiotensinogen.

angiotensin II A peptide hormone formed by the action of angiotensin-converting enzyme on angiotensin I; stimulates aldosterone secretion by the adrenal cortex.

animal pole The non-yolky, metabolically active pole of a vertebrate or echinoderm egg. Compare with *vegetal pole*.

anion (an'-eye-on) A particle with one or more units of negative charge, such as a chloride ion (Cl⁻) or hydroxide ion (OH⁻). Compare with *cation*.

anisogamy (an'-eye-sog'-uh-me) Sexual reproduction involving motile gametes of similar form but dissimilar size. Compare with *isogamy* and *oogamy*.

annelids (an'-eh-lids) Segmented worms with bilateral symmetry and a tubular body that may be partitioned into ringlike segments.

annual plant A plant that completes its entire life cycle in one year or less. Compare with *perennial plant* and *biennial plant*.

Antarctic tundra Treeless biome of Antarctica Peninsula and nearby islands characterized by extremely cold temperatures and containing lichens, mosses, and few vascular plants.

antenna complex The arrangement of chlorophyll, accessory pigments, and pigment-binding proteins into light-gathering units in the thylakoid membranes of photoautotrophic eukaryotes. See *reaction center* and *photosystem*.

antennae (sing., *antenna*) Sensory structures characteristic of some arthropod groups.

anterior Toward the head end of a bilaterally symmetrical animal. Compare with *posterior*.

anterior pituitary The anterior, glandular lobe of the pituitary gland; functions as a classical endocrine gland; secretes growth hormone, prolactin, melanocyte-stimulating hormone, and several tropic hormones. Compare with *posterior pituitary*.

anther (an'-thur) The part of the stamen in flowers that produces microspores and, ultimately, pollen grains.

antheridium (an'-thur-id'-ee-im) (pl., *antheridia*) In plants, the multicellular male gametangium (sex organ) that produces sperm cells. Compare with *archegonium*.

anthocyanins Class of red water-soluble plant pigments.

anthropoid (an'-thra-poid) A member of a suborder of primates that includes monkeys, apes, and humans.

antibody (an'-tee-bod'-ee) A specific protein (immunoglobulin) that recognizes and binds to specific antigens; produced by plasma cells.

antibody-mediated immunity A type of specific immune response in which B cells differentiate into plasma cells and produce antibodies that bind with foreign antigens, leading to the destruction of pathogens. Compare with *cell-mediated immunity*.

anticodon (an'-tee-koh'-don) A sequence of three nucleotides in transfer RNA that is complementary to, and combines with, the three-nucleotide codon.

antidiuretic hormone (ADH) (an'-ty-dy-uh-ret'-ik) A hormone secreted by the posterior lobe of the pituitary that controls the rate of water reabsorption by the kidney.

antigen (an'-tih-jen) Any molecule, usually a protein or large carbohydrate, that is specifically recognized as foreign by cells of the immune system.

antigen-antibody complex The combination of antigen and antibody molecules.

antigen-presenting cell (APC) A cell that displays foreign antigens as well as its own surface proteins. Dendritic cells, macrophages, and B cells are APCs.

antimicrobial peptides Soluble molecules that destroy pathogens.

anti-oncogene See *tumor suppressor gene*.

antioxidants Certain enzymes (e.g., catalase and peroxidase), vitamins, and other substances that destroy free radicals and other reactive molecules. Compare with *oxidants*.

antiparallel Said of a double-stranded nucleic acid in which the 5' to 3' direction of the sugar-phosphate backbone of one strand is reversed in the other strand.

antiporter Membrane carrier protein that transports two types of substances in opposite directions. Compare with *uniporter* and *symporter*.

anus (ay'-nus) The distal end and outlet of the digestive tract.

aorta (ay-or'-tah) The largest and main systemic artery of the vertebrate body; arises from the left ventricle and branches to distribute blood to all parts of the body except the lungs.

aphotic region (ay-fote'-ik) The lower layer of the ocean (deeper than 100 m or so) where light does not penetrate.

apical dominance (ape'-ih-kl) The inhibition of axillary (lateral) buds by a shoot tip.

apical meristem (mehr'-ih-stem) An area of dividing tissue, located at the tip of a shoot or root, that gives rise to primary tissues; apical meristems cause an increase in the length of the plant body. Compare with *lateral meristems*.

apicomplexans A group of parasitic protists that lack structures for locomotion and that produce sporozoites as infective agents; malaria is caused by an apicomplexan.

apoenzyme (ap'-oh-en'-zime) Protein portion of an enzyme; requires the presence of a specific coenzyme to become a complete functional enzyme.

apomixis (ap'-uh-mix'-us) A type of reproduction in which fruits and seeds are formed asexually.

apoplast A continuum consisting of the interconnected, porous plant cell walls, along which water moves freely. Compare with *symplast*.

apoptosis (ap-uh-toe'-sis) Programmed cell death; apoptosis is a normal part of an organism's development and maintenance. Compare with *necrosis*.

aposematic coloration The conspicuous coloring of a poisonous or distasteful organism that enables potential predators to easily see and recognize it. Also called *warning coloration*. Compare with *cryptic coloration*.

aquaporin One of a family of transport proteins located in the plasma membrane that facilitate the rapid movement of water molecules into or out of cells.

aquifer Underground caverns and porous layers of rock in which groundwater is stored.

aquifer depletion Human removal of more groundwater than precipitation or melting snow can replace.

arachnids (ah-rack'-nidz) Eight-legged arthropods, such as spiders, scorpions, ticks, and mites.

arachnoid The middle of the three meningeal layers that cover and protect the brain and spinal cord; see *pia mater* and *dura mater*.

arboreal Living in trees.

arbuscules Tree-like branched structures inside root cells produced by hyphae of endomycorrhizal fungi known as glomeromycetes.

Archaea (ar'-key-ah) One of the two prokaryotic domains. The absence of peptidoglycan in their cell walls sets them apart from the bacteria. Compare with *bacteria*.

Archaean eon The period of Earth's history from the formation of the crust approximately 4 billion years ago, until 2.5 billion years ago; life originated during the Archaean.

archaellum (pl. *archaella*) A unique whiplike structure extending from the cell surface of many archaea; can be rotated to generate swimming movements. Formerly thought to be a type of flagellum.

archaeococins Antimicrobial substances produced by some archaea.

archaeplastids A monophyletic supergroup of eukaryotes with chloroplasts bounded by outer and inner membranes; include red algae, green algae, and land plants.

archegonium (ar'-ke-go'-nee-um) (pl., *archegonia*) In plants, the multicellular female gametangium (sex organ) that contains an egg. Compare with *antheridium*.

archenteron (ark-en'-ter-on) The central cavity of the gastrula stage of embryonic development that is lined with endoderm; primitive digestive system.

archosaurs (ar'-kuh-sors) Lineage of diapsid vertebrates that includes the extinct dinosaurs and flying reptiles, as well as the extant crocodiles (order Crocodilia) and the birds.

arctic tundra See *tundra*.

Ardipithecus ramidus See *australopithecines*.

arterial pulse See *pulse, arterial*.

arteriole (ar-teer'-ee-ole) A very small artery. Vasoconstriction and vasodilation of arterioles help regulate blood pressure.

artery A thick-walled blood vessel that carries blood away from a heart chamber and toward the body organs. Compare with *vein*.

arthropod (ar'-throh-pod) An invertebrate that belongs to phylum Arthropoda; characterized by a hard exoskeleton; a segmented body; and paired, jointed appendages.

artificial insemination The impregnation of a female by artificially introducing sperm from a male.

artificial selection The selection by humans of traits that are desirable in plants or animals and breeding only those individuals that have the desired traits. Compare with *natural selection*.

ascocarp (ass'-koh-karp) The fruiting body of an ascomycete.

ascomycete (ass'-koh-my'-seat) Member of a phylum of fungi characterized by the production of nonmotile asexual conidia and sexual ascospores.

ascospore (ass'-koh-spor) One of a set of sexual spores, usually eight, contained in a special spore case (an ascus) of an ascomycete.

ascus (ass'-kus) A saclike spore case in ascomycetes that contains sexual spores called *ascospores*.

asexual reproduction Reproduction in which there is no fusion of gametes and in which the genetic makeup of parent and of offspring is usually identical. Compare with *sexual reproduction*.

assimilation (of nitrogen) The conversion of inorganic nitrogen (nitrate, NO₃⁻, or ammonia, NH₃) to the organic molecules of living things; part of the nitrogen cycle.

association areas Areas of the brain that link sensory and motor areas; responsible for thought, learning, memory, language abilities, judgment, and personality.

association neuron See *interneuron*.

assortative mating Sexual reproduction in which individuals pair nonrandomly (i.e., select mates on the basis of phenotype); selection may be positive (mates with the same phenotype) or less commonly negative (mates with opposite phenotypes).

asters Clusters of microtubules radiating out from the poles in dividing cells that have centrioles.

astrocyte A type of glial cell; some are phagocytic; others regulate the composition of the extracellular fluid in the central nervous system.

atherosclerosis (ath'-ur-oh-skle-row'-sis) A progressive disease in which lipid deposits accumulate in the inner lining of arteries, leading eventually to impaired circulation and heart disease.

atom The smallest quantity of an element that retains the chemical properties of that element.

atomic mass The total number of protons and neutrons in an atom; expressed in atomic mass units or daltons.

atomic mass unit (amu) The approximate mass of a proton or neutron; also called a *dalton*.

atomic number The number of protons in the atomic nucleus of an atom, which uniquely identifies the element to which the atom corresponds.

ATP See *adenosine triphosphate*.

ATP synthase Large enzyme complex that catalyzes the formation of ATP from ADP and inorganic phosphate by chemiosmosis; located in the inner mitochondrial membrane, the thylakoid membrane of chloroplasts, and the plasma membrane of prokaryotes.

atrial natriuretic peptide (ANP) A hormone released by the atrium of the heart; helps regulate sodium excretion and lowers blood pressure.

atrioventricular (AV) node (ay'-tree-oh-ven-trik'-you-lur) Mass of specialized cardiac tissue that receives an impulse from the sinoatrial node (pacemaker) and conducts it to the ventricles.

atrioventricular (AV) valve (of the heart) A valve between each atrium and its ventricle that prevents backflow of blood. The right AV valve is the tricuspid valve; the left AV valve is the mitral valve.

atrium (of the heart) (ay'-tree-um) A heart chamber that receives blood from the veins.

australopithecines Early hominids that lived between about 6 mya and 1 mya, based on fossil evidence. Include several species in three genera: *Ardipithecus*, *Australopithecus*, and *Paranthropus*.

Australopithecus afarensis See *australopithecines*.

Australopithecus africanus See *australopithecines*.

Australopithecus anamensis See *australopithecines*.

Australopithecus sediba See *australopithecines*.

autocrine regulation A type of regulation in which a signaling molecule (e.g., a hormone) is secreted into interstitial fluid and then acts on the cells that produce it. Compare with *paracrine regulation*.

autoimmune disease (aw'-toh-ih-mune') A disease in which the body produces antibodies against its own cells or tissues. Also called *autoimmunity*.

autonomic division (of the PNS) (aw-tuh-nom'-ik) The portion of the peripheral nervous system that controls the visceral functions of the body (e.g., regulates smooth muscle, cardiac muscle, and glands). The autonomic division is subdivided into the sympathetic and parasympathetic systems. Compare with *somatic division (of the PNS)*.

autophagy A cellular process in which lysosomes digest, process, and recycle the contents of unneeded or damaged cellular components.

autopolyploid A polyploid whose chromosomes are derived from a single species. Compare with *allopolyploid*.

autoradiography Method for detecting radioactive decay; radiation causes the appearance of dark silver grains in special X-ray film.

autosome (aw'-toh-sohm) A chromosome other than the sex (X and Y) chromosomes.

autotroph (aw'-toh-trof) An organism that synthesizes complex organic compounds from simple inorganic raw materials; also called *producer* or *primary producer*. Compare with *heterotroph*. See *chemoautotroph* and *photoautotroph*.

auxin (awk'-sin) A plant hormone involved in various aspects of growth and development, such as stem elongation, apical dominance, and root formation on cuttings (e.g., indole acetic acid [IAA]).

avirulence Properties that render an infectious agent nonlethal (i.e., unable to cause disease in its host). Compare with *virulence*.

Avogadro's number The number of units (6.02×10^{23}) present in one mole of any substance.

axillary bud A bud in the axil of a leaf; also called *lateral bud*. Compare with *terminal bud*.

axon (aks'-on) The long extension of the neuron that transmits nerve impulses away from the cell body. Compare with *dendrite*.

axopods (aks'-o-podz) Long, filamentous, cytoplasmic projections characteristic of actinopods.

B cell (B lymphocyte) The type of white blood cell responsible for antibody-mediated immunity. When stimulated, B cells differentiate to become plasma cells that produce antibodies. Compare with *T cell*.

bacillus (bah-sill'-us) (pl., *bacilli*) A rod-shaped bacterium. Compare with *coccus*, *spirillum*, *vibrio*, and *spirochete*.

background extinction The continuous, low-level extinction of species that has occurred throughout much of the history of life. Compare with *mass extinction*.

bacteria (bak-teer'-ee-ah) Prokaryotic organisms that have peptidoglycan in their cell walls; most are decomposers, but some are parasites and others are autotrophs. Bacteria is the name of one of the two prokaryotic domains. Compare with *archaea*.

bacterial artificial chromosome (BAC) Genetically engineered segments of chromosomal DNA with the ability to carry large segments of foreign DNA.

bacteriophage (bak-teer'-ee-oh-fayj) A virus that infects a bacterium (literally, "bacteria eater"). Also called *phage*.

balanced polymorphism (pol'-ee-mor'-fizm) The presence in a population of two or more genetic variants that are maintained in a stable frequency over several generations.

bark The outermost covering over woody stems and roots; consists of all plant tissues located outside the vascular cambium.

baroreceptors (bare"-oh-ree-sep'-torz) Receptors within certain blood vessels that are stimulated by changes in blood pressure.

Barr body A condensed and inactivated X chromosome appearing as a distinctive dense spot in the interphase nucleus of certain cells of female mammals.

basal angiosperms (bay'-sl) Three clades of angiosperms that are thought to be ancestral to all other flowering plants. Compare with *core angiosperms*.

basal body Structure involved in the organization and anchorage of a cilium or flagellum. Structurally similar to a centriole; each is in the form of a cylinder composed of nine triplets of microtubules (9×3 structure).

basal metabolic rate (BMR) The amount of energy expended by the body at resting conditions, when no food is being digested and no voluntary muscular work is being performed.

base (1) A substance that is a hydrogen ion (proton) acceptor; bases unite with acids to form salts. Compare with *acid*. (2) A nitrogenous base in a nucleotide or nucleic acid. See *purines* and *pyrimidines*.

basement membrane The thin, noncell layer of an epithelial membrane that attaches to the underlying tissues; consists of tiny fibers and polysaccharides produced by the epithelial cells.

base-pair substitution mutation A change in one base pair in DNA. See *missense mutation* and *nonsense mutation*.

basic solution A solution in which the concentration of hydroxide ions $[\text{OH}^-]$ exceeds the concentration of hydrogen ions $[\text{H}^+]$. A basic solution has a pH greater than 7. Compare with *acidic solution* and *neutral solution*.

basidiocarp (ba-sid'-ee-o-karp) The fruiting body of a basidiomycete (e.g., a mushroom).

basidiomycete (ba-sid'-ee-o-my'-seat) Member of a phylum of fungi characterized by the production of sexual basidiospores.

basidiospore (ba-sid'-ee-o-spor) One of a set of sexual spores, usually four, borne on a basidium of a basidiomycete.

basidium (ba-sid'-ee-um) The clublike spore-producing organ of basidiomycetes that bears sexual spores called *basidiospores*.

basilar membrane The multicellular tissue in the inner ear that separates the cochlear duct from the tympanic canal; the sensory cells of the organ of Corti rest on this membrane.

Batesian mimicry (bate'-see-un mim'-ih-kree) The resemblance of a harmless or palatable species to one that is dangerous, unpalatable, or poisonous so that predators are more likely to avoid them. Compare with *Müllerian mimicry*.

B-cell receptors The receptors on B cells that recognize specific antigens.

behavior What an animal does and how the animal does it, usually in response to stimuli in the environment.

behavioral ecology The scientific study of behavior in natural environments from the evolutionary perspective.

behavioral isolation A prezygotic reproductive isolating mechanism in which reproduction between similar species is prevented because each group exhibits its own characteristic courtship behavior; also called *sexual isolation*.

behavior pattern A fixed behavior that, once activated, continues to completion regardless of sensory feedback.

benthic environment Ocean floor divided into zones based on distance from land, light availability, and depth.

benthos (ben'-thos) Bottom-dwelling sea organisms that fix themselves to one spot, burrow into the sediment, or simply walk about on the ocean floor.

berry A simple, fleshy fruit in which the fruit wall is soft throughout (e.g., tomato, banana, grape).

beta cells Pancreatic cells that secrete insulin.

beta (β) oxidation Process by which fatty acids are converted to acetyl CoA before entry into the citric acid cycle.

beta (β)-pleated sheet A regular, folded, sheetlike type of protein secondary structure, resulting from hydrogen bonding between two different polypeptide chains or two regions of the same polypeptide chain. Compare with *alpha (α) helix*.

biennial plant (by-en'-ee-ul) A plant that takes two years to complete its life cycle. Compare with *annual plant* and *perennial plant*.

bikonts One of two main clades of all eukaryotes; had a common ancestor with two flagella. Compare with *unikonts*.

bilateral symmetry A body shape with right and left halves that are approximately mirror images of each other. Compare with *radial symmetry*.

bile The fluid secreted by the liver; emulsifies fats.

binary fission (by'-nare-ee fish'-un) Equal division of a prokaryotic cell into two; a type of asexual reproduction.

binomial system of nomenclature (by-nome'-ee-ul) System of naming a species by the combination of the genus name and a specific epithet.

bioaccumulation The buildup of a persistent toxic substance, such as certain pesticides, in an organism's body.

biodiversity See *biological diversity*.

biodiversity hotspot Biogeographic region that is a significant reservoir of endemic biodiversity and is threatened with continued habitat destruction.

biofilm An irregular layer of microorganisms embedded in the slime they secrete and concentrated at a solid or liquid surface.

biogenic amines A class of neurotransmitters that includes norepinephrine, serotonin, and dopamine.

biogeochemical cycle (bye"-o-jee"-o-kem'-ee-kl) Process by which matter cycles from the living world to the nonliving, physical environment and back again (e.g., the carbon cycle, the nitrogen cycle, and the phosphorus cycle).

biogeography The study of the past and present geographic distributions of organisms.

bioinformatics The storage, retrieval, and comparison of biological information, particularly DNA or protein sequences within a given species and among different species.

biological clocks Mechanisms by which activities of organisms are adapted to regularly recurring changes in the environment. See *circadian rhythm*.

biological diversity The variety of living organisms considered at three levels: genetic diversity, species diversity, and ecosystem diversity. Also called *biodiversity*.

biological magnification The increased concentration of toxic chemicals, such as PCBs, heavy metals, and certain pesticides, in the tissues of organisms at higher trophic levels in food webs.

biological species concept See *species*.

biomass (bye'-o-mas) A quantitative estimate of the total mass, or amount, of living material in a particular ecosystem.

biome (by'-ohm) A large, relatively distinct terrestrial region characterized by a similar climate, soil, plants, and animals, regardless of where it occurs on Earth.

bioremediation A method to clean up a hazardous waste site that uses microorganisms to break down toxic pollutants, or plants to selectively accumulate toxins.

biosphere All Earth's communities of living organisms and their physical environments.

biosphere reserves Zones designed and set aside to protect biodiversity, promote sustainable development, and foster research and conservation education.

bioterrorism The intentional use of biological agents, such as microorganisms or toxins derived from living organisms, to cause death or disease.

biotic factors Elements of the living world that affect a particular organism (i.e., its relationships with other organisms). Compare with *abiotic factors*.

biotic pollution Introduction of a foreign species into an area where it is not native.

biotic potential See *intrinsic rate of increase*.

bipedal Walking on two feet. Compare with *quadrupedal*.

bipolar cell A type of neuron in the retina of the eye; receives input from the photoreceptors (rods and cones) and synapses on ganglion cells.

biramous appendages Appendages with two jointed branches extending from their base. Compare with *uniramous appendages*.

blade (1) The thin, expanded part of a leaf. (2) The flat, leaflike structure of certain multicellular algae.

blastocoel (blas'-toh-seel) The fluid-filled cavity of a blastula.

blastocyst The mammalian blastula. See *blastula*.

blastodisc A small disc of cytoplasm at the animal pole of a reptile or bird egg; cleavage is restricted to the blastodisc (meroblastic cleavage).

blastomere A cell of an early embryo.

blastopore (blas'-toh-pore) The primitive opening into the body cavity of an early embryo that may become the mouth (in protostomes) or anus (in deuterostomes) of the adult organism.

blastula (blas'-tew-lah) In animal development, a hollow ball of cells produced by cleavage of a fertilized ovum. In mammalian development, known as a *blastocyst*.

blood A fluid, circulating connective tissue that transports nutrients and other materials through the bodies of many types of animals.

blood pressure The force exerted by blood against the inner walls of the blood vessels.

bloom The sporadic occurrence of huge numbers of algae in freshwater and marine ecosystems.

body mass index (BMI) An index of weight in relation to height; calculated by dividing the square of the weight (square kilograms) by height (meters).

Bohr effect Increased oxyhemoglobin dissociation due to lowered pH; occurs as carbon dioxide concentration increases.

bolting The production of a tall flower stalk by a plant that grows vegetatively as a rosette (growth habit with a short stem and a circular cluster of leaves).

bond energy The energy required to break a particular chemical bond.

bone Principal vertebrate skeletal tissue; a type of connective tissue that consists of cells (osteocytes) embedded in a hard matrix of collagen fibers and minerals, including calcium and phosphate.

bone marrow The soft, cellular tissue that fills the internal spaces of bones; red bone marrow in certain bones produces blood cells.

boreal forest (bor'-ee-uhl) The northern coniferous forest biome found primarily in Canada, northern Europe, and Siberia; also called *taiga*.

bottleneck A sudden decrease in a population size caused by adverse environmental factors; may result in genetic drift; also called *genetic bottleneck* or *population bottleneck*.

bottom-up processes Control of ecosystem function by nutrient cycles and other parts of the abiotic environment. Compare with *top-down processes*.

Bowman's capsule A double-walled sac of cells that surrounds the glomerulus of each nephron.

brachiopods (bray'-kee-oh-podz) The phylum of solitary marine invertebrates having a pair of shells and, internally, a pair of coiled arms with ciliated tentacles; one of the lophophorate phyla.

bracts Modified leaves associated with flower clusters; may be showy and petal-like.

brain A concentration of nervous tissue that controls neural function; in vertebrates, the anterior, enlarged portion of the central nervous system.

brain stem The part of the vertebrate brain that includes the medulla, pons, and midbrain.

branchial Pertaining to the gills or gill region.

brassinosteroid (BR) One of a group of steroids that function as plant hormones and are involved in several aspects of growth and development.

Broca's area Located near motor areas in the left frontal lobe; controls our ability to speak; important in language processing and speech comprehension.

bronchiole (brank'-ee-ole) Air duct in the lung that branches from a bronchus; divides to form air sacs (alveoli).

bronchus (brank'-us) (pl., *bronchi*) One branch of the trachea and its immediate branches within the lung.

brown alga One of a group of predominantly marine algae that are multicellular and contain the pigments chlorophyll *a* and *c*, and carotenoids, including fucoxanthin.

bryophytes (bry'-oh-fites) Nonvascular plants including mosses, liverworts, and hornworts.

bryozoans Animals belonging to phylum Bryozoa, one of the three lophophorate phyla; form sessile colonies by asexual budding.

bud An undeveloped shoot that develops into flowers, stems, or leaves. Buds are enclosed in bud scales; see *axillary bud* and *terminal bud*.

budding Asexual reproduction in which a small part of the parent's body separates from the rest and develops into a new individual; characteristic of yeasts and certain other organisms.

bud scale A modified leaf that covers and protects a dormant bud.

bud scale scar Scar on a twig left when a bud scale abscises from the terminal bud.

buffer A substance in a solution that tends to lessen the change in hydrogen ion concentration (pH) that otherwise would be produced by adding an acid or base.

bulb A globose, fleshy, underground bud that consists of a short stem with fleshy leaves (e.g., onion).

bundle scar Marks on a leaf scar left when vascular bundles of the petiole break during leaf abscission.

bundle sheath Group of tightly packed cells that form a sheath around the veins of a leaf.

bundle sheath extension Group of support cells that extend from the bundle sheath of a leaf vein toward the upper and/or lower epidermis.

buttress root A bracelike root at the base of certain trees that provides upright support.

C₃ pathway See *C₃ plant*.

C₃ plant Plant that carries out carbon fixation solely by the Calvin cycle. Compare with *C₄ plant* and *CAM plant*.

C₄ pathway See *C₄ plant*.

C₄ plant Plant that fixes carbon initially by a pathway in which the reaction of CO₂ with phosphoenolpyruvate is catalyzed by PEP carboxylase in leaf mesophyll cells; the products are transferred to the bundle sheath cells, where the Calvin cycle takes place. Compare with *C₃ plant* and *CAM plant*.

cadherins Transmembrane proteins that are components of adhering junctions between animal cells.

calcitonin (kal-sih-toh'-nin) A hormone secreted by the thyroid gland that rapidly lowers the calcium content in the blood.

calls Short, simple sounds animals use to communicate.

callus (kal'-us) Undifferentiated tissue formed on an explant (excised tissue or organ) in plant tissue culture.

calmodulin A calcium-binding protein; when bound, it alters the activity of certain enzymes or transport proteins.

calorie The amount of heat energy required to raise the temperature of 1 g of water 1°C; equivalent to 4.184 joules. Compare with *kilocalorie*.

Calvin cycle Cyclic series of reactions in the chloroplast stroma in photosynthesis; fixes carbon dioxide and produces carbohydrate. See *C₃ plant*.

calyx (kay'-liks) The collective term for the sepals of a flower.

cambium See *lateral meristems*.

Cambrian explosion See *Paleozoic era*.

Cambrian period See *Paleozoic era*.

Cambrian radiation See *Paleozoic era*.

cAMP See *cyclic AMP*.

CAM plant Plant that carries out crassulacean acid metabolism; carbon is initially fixed into organic acids at night in the reaction of CO₂ and phosphoenolpyruvate, catalyzed by PEP carboxylase; during the day the acids break down to yield CO₂, which enters the Calvin cycle. Compare with *C₃ plant* and *C₄ plant*.

cGMP See *cyclic GMP*.

cancer cells See *malignant cells*.

cancer driver gene A gene that, when its expression is altered, either by a particular mutation or by certain epigenetic changes, gives a cell a selective growth advantage. See *oncogene*, *proto-oncogene*, and *tumor suppressor gene*.

canines The long pointed teeth of a mammal adapted for piercing prey and tearing food. Compare with *incisors*, *premolars*, and *molars*.

CAP See *catabolite activator protein*.

capacitation Maturation process that enables mammalian sperm to participate in fertilization; takes place in the female reproductive tract.

capillaries (kap'-i-lare-eez) Microscopic blood vessels in the tissues that permit exchange of materials between cells and blood.

capillary action The ability of water to move in small-diameter tubes as a consequence of its cohesive and adhesive properties.

capping See *mRNA cap*.

capsid Protein coat surrounding the nucleic acid of a virus.

capsule (1) The portion of the moss sporophyte that contains spores. (2) A simple, dry, dehiscent fruit that develops from two or more fused carpels and opens along many sutures or pores to release seeds. (3) A gelatinous coat that surrounds some bacteria.

carbohydrate Compound containing carbon, hydrogen, and oxygen, in the approximate ratio of C:2H:O (e.g., sugars, starch, and cellulose).

carbon cycle The worldwide circulation of carbon from the abiotic environment into living things and back into the abiotic environment.

carbon fixation reactions Reduction reactions of photosynthesis in which carbon from carbon dioxide becomes incorporated into organic molecules, leading to the production of carbohydrate. See *Calvin cycle*.

Carboniferous period See *Paleozoic era*.

carbonyl group A polar functional group consisting of a carbon attached to an oxygen by a double bond; found in aldehydes and ketones.

carboxyl group A weakly acidic functional group; abbreviated —COOH.

carcinogen (kar-sin'-oh-jen) An agent that causes cancer or accelerates its development.

cardiac cycle One complete heartbeat.

cardiac muscle Involuntary, striated type of muscle found in the vertebrate heart. Compare with *smooth muscle* and *skeletal muscle*.

cardiac output The volume of blood pumped by the left ventricle into the aorta in 1 minute.

cardiovascular disease Disease of the heart or blood vessels; the leading cause of death in most industrial societies.

cardiovascular system The closed circulatory system of vertebrates that transports oxygen, nutrients, hormones, and other substances, and protects the body against disease; consists of heart and blood vessels.

carnivore (kar'-ni-vor) An animal that mainly feeds on other animals; a mammal belonging to order Carnivora (e.g., wolves or seals).

carotenoids (ka-rot'-n-oidz) A group of yellow to orange plant pigments synthesized from isoprene subunits; include carotenes and xanthophylls.

carpel (kar'-pul) The female reproductive unit of a flower; carpels bear ovules. Compare with *pistil*.

carrier-mediated active transport Transport across a membrane of a substance from a region of low concentration to a region of high concentration; requires both a transport protein with a binding site for the specific substance and an energy source (often ATP).

carrier-mediated transport Any form of transport across a membrane that uses a membrane-bound transport protein with a binding site for a specific substance; includes both facilitated diffusion and carrier-mediated active transport.

carrying capacity (K) The largest population that a particular habitat can support and sustain for an indefinite period, assuming there are no changes in the environment.

cartilage A flexible skeletal tissue of vertebrates; a type of connective tissue.

caryopsis (pl., *caryopses*) See *grain*.

Cas A ribonucleoprotein endonuclease encoded within a CRISPR locus in prokaryotic DNA.

Casparian strip (kas-pare'-ee-un) A band of waterproof material around the radial and transverse walls of endodermal root cells.

caspase Any of a group of proteolytic enzymes that are active in the early stages of apoptosis.

catabolism The aspect of metabolism in which complex substances are broken down to form simpler substances; catabolic reactions are particularly important in releasing chemical energy stored by the cell. Compare with *anabolism*.

catabolite activator protein (CAP) A positively acting regulator that becomes active when bound to cAMP; active CAP stimulates transcription of the *lac* operon and other operons that code for enzymes used in catabolic pathways.

catalyst (kat'-ah-list) A substance that increases the speed at which a chemical reaction occurs without being used up in the reaction. Enzymes are biological catalysts.

catecholamine (cat'-eh-kole'-ah-meen) A class of compounds including dopamine, epinephrine, and norepinephrine; these compounds serve as neurotransmitters and hormones.

cation A particle with one or more units of positive charge, such as a hydrogen ion (H⁺) or calcium ion (Ca²⁺). Compare with *anion*.

cation exchange Process in which root cells secrete protons (H⁺), which replace cations adhering to soil particles, thereby releasing them for absorption by the roots.

cecum (see'-kum) The blind pouch formed at the junction of the small and large intestine.

CD4 T cell See *T helper cell*.

CD8 T cell See *T cytotoxic cell*.

cDNA See *complementary DNA*.

cell The basic structural and functional unit of life, which consists of living material enclosed by a membrane.

cell body The large portion of a neuron that contains most of the cytoplasm, the nucleus, and most of the other organelles.

cell cycle Cyclic series of events in the life of a dividing eukaryotic cell; consists of mitosis, cytokinesis, and the stages of interphase.

cell-cycle checkpoints See *cell-cycle control system*.

cell-cycle control system Regulatory molecules that control key events (cell-cycle checkpoints) in the cell cycle; common to all eukaryotes.

cell determination See *determination*.

cell differentiation See *differentiation*.

cell fractionation The technique used to separate the components of cells by subjecting them to centrifugal force. See *differential centrifugation* and *density gradient centrifugation*.

cell-mediated immunity A type of specific immune response carried out by T cells. Compare with *antibody-mediated immunity*.

cell plate The structure that forms during cytokinesis in plants, separating the two daughter cells produced by mitosis.

cell signaling Mechanisms of communication between cells. Cells signal one another with secreted signaling molecules, or a signaling molecule on one cell combines with a receptor on another cell. See *signal transduction*.

cell theory The scientific theory that the cell is the basic unit of life, of which all living things are composed, and that all cells are derived from pre-existing cells.

cellular respiration See *respiration*.

cellular slime mold A group of funguslike amoeboid protists whose feeding stage consists of unicellular, amoeboid organisms that aggregate to form a pseudoplasmodium during reproduction; compare with *plasmoidal slime mold*.

cellulose (sel'-yoo-lohs) A structural polysaccharide consisting of beta glucose subunits; the main constituent of plant primary cell walls.

cell wall The structure outside the plasma membrane of certain cells; may contain cellulose (plant cells), chitin (most fungal cells), peptidoglycan and/or lipopolysaccharide (most bacterial cells), or other material.

Cenozoic era Span of geologic time extending from 66 mya to the present; marked by diversification of mammals, birds, insects, and flowering plants. Divided into Paleogene (66–23 mya), Neogene (23–2.6 mya), and Quaternary (2.6 mya to present) periods.

center of origin The geographic area where a given species originated.

central nervous system (CNS) In vertebrates, the brain and spinal cord. Compare with *peripheral nervous system*.

centrifuge A device used to separate cells or their components by subjecting them to centrifugal force.

centriole (sen'-tree-ohl) One of a pair of small, cylindrical organelles lying at right angles to each

other near the nucleus in the cytoplasm of animal cells and certain protist and plant cells; each centriole is in the form of a cylinder composed of nine triplets of microtubules (9 × 3 structure).

centromere (sen'-tro-meer) A specialized constricted region of a chromatid; contains the kinetochore. In cells at prophase and metaphase, sister chromatids are joined in the vicinity of their centromeres.

centrosome (sen'-tro-sowm) An organelle in animal cells that is the main microtubule-organizing center; typically contains a pair of centrioles and is important in cell division.

cephalization The evolution of a head; the concentration of nervous tissue and sense organs at the front end of the animal.

cephalochordates Members of the chordate subphylum that includes the lancelets.

cerebellum (ser-eh-bel'-um) A convoluted subdivision of the vertebrate brain concerned with coordination of muscular movements, muscle tone, and balance.

cerebral cortex (ser-ee'-brul kor'-teks) The outer layer of the cerebrum composed of gray matter and consisting mainly of nerve cell bodies.

cerebrospinal fluid (CSF) The fluid that bathes the central nervous system of vertebrates.

cerebrum (ser-ee'-brum) A large, convoluted subdivision of the vertebrate brain; in humans, it functions as the center for learning, voluntary movement, and interpretation of sensation.

cervix The lower region of the uterus; extends slightly into the vagina.

chaparral (shap'-uh-ral') A biome with a Mediterranean climate (mild, moist winters and hot, dry summers). Chaparral vegetation is characterized by drought-resistant, small-leaved evergreen shrubs and small trees.

chaperones See *molecular chaperones*.

character An attribute or characteristic of an organism.

character displacement The tendency for two similar species to diverge (become more different) in areas where their ranges overlap; reduces interspecific competition.

Chargaff's rules A relationship in DNA molecules based on nucleotide composition data; the number of adenines equals the number of thymines, and the number of guanines equals the number of cytosines.

charophytes Group of green algae closely related to land plants.

chelicerae (keh-lis'-er-ee) The first pair of appendages in certain arthropods; clawlike appendages located immediately anterior to the mouth and used to manipulate food into the mouth.

chemical bond A force of attraction between atoms in a compound. See *covalent bond*, *hydrogen bond*, and *ionic bond*.

chemical compound Two or more elements combined in a fixed ratio.

chemical evolution The origin of life from nonliving matter.

chemical formula A representation of the composition of a compound; the elements are indicated by chemical symbols with subscripts to indicate their ratios. See *molecular formula*, *structural formula*, and *simplest formula*.

chemical symbol The abbreviation for an element; usually the first letter (or first and second letters) of the English or Latin name.

chemical synapse A junction between two neurons in which an action potential in the presynaptic neuron triggers release of a neurotransmitter that crosses the gap and binds to a receptor on the postsynaptic neuron; specific gated ion channels open or close, which changes the permeability of the postsynaptic neuron. When threshold level is reached, the postsynaptic neuron transmits an action potential. Compare with *electrical synapse*.

chemiosmosis Process by which phosphorylation of ADP to form ATP is coupled to the transfer of electrons down an electron transport chain; the electron transport chain powers proton pumps that produce a proton gradient across the membrane; ATP is formed as protons diffuse through transmembrane channels in ATP synthase.

chemoautotroph (kee"-moh-aw'-toh-trof) Organism that obtains energy from inorganic compounds and synthesizes organic compounds from inorganic raw materials; includes some bacteria and many archaea. Compare with *photoautotroph*, *photoheterotroph*, and *chemoheterotroph*.

chemoheterotroph (kee"-moh-het'-ur-oh-trof) Organism that uses organic compounds as a source of energy and carbon; includes animals, fungi, many bacteria, and a few archaea. Compare with *photoautotroph*, *photoheterotroph*, and *chemoautotroph*.

chemoreceptor (kee"-moh-ree-sep'-tor) A sensory receptor that responds to chemical stimuli.

chemotaxis Movement of a cell or organism in response to certain chemicals.

chemotroph (kee'-moh-trof) Organism that uses organic compounds or inorganic substances, such as iron, nitrate, ammonia, or sulfur, as sources of energy. Compare with *phototroph*. See *chemoautotroph* and *chemoheterotroph*.

chiasma (ky-az'-muh) (pl., *chiasmata*) An X-shaped site in a tetrad usually marking the location where homologous (nonsister) chromatids previously crossed over.

chimera (ky-meer'-uh) An organism consisting of two or more kinds of genetically dissimilar cells.

chitin (ky'-tin) A nitrogen-containing structural polysaccharide that forms the exoskeleton of insects and the cell walls of many fungi.

chlorophyll (klor'-oh-fil) A group of light-trapping green pigments found in most photosynthetic organisms.

chlorophyll a See *chlorophyll*.

chlorophyll b See *chlorophyll*.

chlorophyll-binding proteins About 15 different proteins associated with chlorophyll molecules in the thylakoid membrane.

chloroplasts (klor'-oh-plastz) Membranous organelles that are the sites of photosynthesis in eukaryotes; occur in some plant and algal cells.

choanocyte (ko-an'-uh-site) A collared, flagellate cell that traps and phagocytizes food particles; found in sponges; also called a *collar cell*.

choanoflagellates Collared flagellate protists; opisthokonts closely related to animals.

cholinergic neuron (kohl"-in-air'-jik) A neuron that releases acetylcholine as a neurotransmitter. Compare with *adrenergic neuron*.

chondrichthyes (kon-drik'-thees) The class of cartilaginous fishes that includes the sharks, rays, and skates.

chondrocytes Cartilage cells.

chordates (kor'-dates) Deuterostome animals that, at some time in their lives, have a cartilaginous, dorsal skeletal structure called a *notochord*; a dorsal, tubular nerve cord; *pharyngeal slits*; a postanal tail; and an *endostyle* (or its derivative, a thyroid gland).

chorion (kor-'ee-on) An extraembryonic membrane in reptiles, birds, and mammals that forms an outer cover around the embryo and in mammals contributes to the formation of the placenta.

chorionic villus sampling (CVS) (kor"ee-on'ik) Study of extraembryonic cells that are genetically identical to the cells of an embryo, making it possible to assess its genetic makeup. Compare with *amniocentesis*.

choroid layer A layer of cells filled with black pigment that absorbs light and prevents reflected light from blurring the image that falls on the retina; the layer of the eyeball outside the retina.

chromalveolates A supergroup composed of diverse protists with few shared characters; most are photosynthetic, and heterotrophic chromalveolates, such as the water molds and ciliates, probably descended from autotrophic ancestors. Divided into two main groups; see *alveolates* and *stramenopiles*.

chromatid (kroh'-mah-tid) One of the two identical halves of a duplicated chromosome; the two chromatids that make up a chromosome are referred to as *sister chromatids*.

chromatin (kro'-mah-tin) The complex of DNA and protein that makes up eukaryotic chromosomes.

chromoplasts Pigment-containing plastids; found mainly in flowers and fruits.

chromosome theory of inheritance A basic principle in biology that states that inheritance can be explained by assuming that genes are linearly arranged in specific locations along the chromosomes.

chromosomes Structures in the cell nucleus that consist of chromatin and contain the genes. The chromosomes become visible under the microscope as distinct structures during cell division.

chylomicrons (kie-low-my'-kronz) Protein-covered fat droplets produced in the intestinal cells; they enter the lymphatic system and are transported to the blood.

chytrid See *chytridiomycete*.

chytridiomycete (ki-trid"-ee-o-my'-seat) A member of a phylum of fungi characterized by the production of flagellate cells at some stage in their life history. Also called *chytrid*.

ciliate (sil'-e-ate) A unicellular protist covered by many short cilia.

cilium (sil'-ee-um) (pl., *cilia*) One of many short, hairlike structures that project from the surface of some eukaryotic cells and are used for locomotion or movement of materials across the cell surface.

circadian rhythm (sir-kay'-dee-un) An internal rhythm that approximates the 24-hour day. See *biological clocks*.

circulatory system The body system that functions in internal transport and protects the body from disease.

cisternae (sing., *cisterna*) Stacks of flattened membranous sacs that make up the Golgi complex.

citrate (citric acid) A 6-carbon organic acid.

citric acid cycle Series of chemical reactions in aerobic cellular respiration in which acetyl coenzyme A is completely degraded to carbon dioxide and water with the release of metabolic energy that is used to produce ATP; also known as the *Krebs cycle* and the *tricarboxylic acid (TCA) cycle*.

clade A group of organisms containing a common ancestor and all its descendants; a monophyletic group.

cladistics An approach to classification based on recency of common ancestry rather than degree of structural similarity. Also called *phylogenetic systematics*. Compare with *phenetics* and *evolutionary systematics*.

cladogram A branching diagram that illustrates taxonomic relationships based on the principles of cladistics.

class A taxonomic category made up of related orders.

classical conditioning A type of learning in which an association is formed between some normal response to a stimulus and a new stimulus, after which the new stimulus elicits the response.

cleavage Series of mitotic cell divisions, without growth, that converts the zygote to a multicellular blastula.

cleavage furrow A constricted region of the cytoplasm that forms and progressively deepens during cytokinesis of animal cells, thereby separating the two daughter cells.

climate Average weather conditions, plus extremes (records), that occur in a given place over a period of years.

climate change Change in Earth's climate patterns; today mostly caused by increased levels of atmospheric carbon dioxide produced by use of fossil fuels.

cline Gradual change in phenotype and genotype frequencies among contiguous populations that is the result of an environmental gradient.

clitoris (klit'-o-ris) A small, erectile structure at the anterior part of the vulva in female mammals; homologous to the male penis.

cloaca (klow-a'-ka) An exit chamber in some animals that receives digestive wastes and urine; may also serve as an exit for gametes.

clonal expansion The increase in number of T cells or B cells specific for an antigen; occurs when specific T cells or B cells are activated by the antigen.

clonal selection Lymphocyte activation in which a specific antigen causes activation, cell division, and differentiation only in cells that express receptors with which the antigen binds.

clone (1) A population of cells descended by mitotic division from a single ancestral cell. (2) A population of genetically identical organisms asexually propagated from a single individual. Also see *DNA cloning*.

cloning The process of forming a clone.

closed circulatory system A type of circulatory system in which the blood flows through a continuous circuit of blood vessels; characteristic of annelids, cephalopods, and vertebrates. Compare with *open circulatory system*.

closed system An entity that does not exchange energy with its surroundings. Compare with *open system*.

club mosses A phylum of seedless vascular plants with a life cycle similar to that of ferns.

clumped dispersion The spatial distribution pattern of a population in which individuals are more concentrated in specific parts of the habitat. Also called *aggregated distribution* and *patchiness*. Compare with *random dispersion* and *uniform dispersion*.

cnidarians (ni-dah'-ree-anz) Phylum of animals that have stinging cells called *cnidocytes*, two tissue layers, and radial symmetry; include hydras and jellyfish.

cnidocytes Stinging cells characteristic of cnidarians.

coated pit A depression in the plasma membrane, the cytosolic side of which is coated with the protein clathrin; important in receptor-mediated endocytosis.

coccus (kok'-us) (pl., *cocci*) A bacterium with a spherical shape. Compare with *bacillus*, *spirillum*, *vibrio*, and *spirochete*.

cochlea (koke'-lee-ah) The structure of the inner ear of mammals that contains the auditory receptors (organ of Corti).

codominance (koh"-dom'-in-ants) Condition in which two alleles of a locus are expressed in a heterozygote.

codon (koh'-don) A triplet of mRNA nucleotides. The 64 possible codons collectively constitute a universal genetic code in which each codon specifies an amino acid in a polypeptide, or a signal to either start or terminate polypeptide synthesis.

coelacanth A genus of lobe-finned fishes that has survived to the present day.

coelom (see'-lum) The main body cavity of most animals; a true coelom is lined with mesoderm. Compare with *pseudocoelom*.

coelomate (seel'-oh-mate) Animal that has a true coelom. Compare with *acoelomate* and *pseudocoelomate*.

coenocyte (see'-no-site) An organism consisting of a multinucleate cell (i.e., the nuclei are not separated from one another by septa).

coenzyme (koh-en'-zime) An organic cofactor for an enzyme; generally participates in the reaction by transferring some component, such as electrons or part of a substrate molecule.

coenzyme A (CoA) Organic cofactor responsible for transferring groups derived from organic acids.

coevolution The reciprocal adaptation of two or more species that occurs as a result of their close interactions over a long period.

cofactor A nonprotein substance needed by an enzyme for normal activity; some cofactors are inorganic (usually metal ions); others are organic (coenzymes).

cognition The mental processes involved in gaining and using knowledge; cognition is learning and knowing, including awareness, thinking,

processing information, reasoning, and awareness of thoughts, perceptions, and self.

cohesin Ring-shaped protein complex responsible for linking sister chromatids during prophase.

cohesion The property of sticking together. Compare with *adhesion*.

cohort A group of individuals of the same age.

colchicine A drug that blocks the division of eukaryotic cells by binding to tubulin subunits, which make up the microtubules, the major component of the mitotic spindle.

coleoptile (kol-ee-op'-tile) A protective sheath that encloses the young stem in certain monocots.

collagens (kol'-ah-genz) Proteins found in the collagen fibers of connective tissues.

collar cell See *choanocyte*.

collecting duct A tube in the kidney that receives filtrate from several nephrons and conducts it to the renal pelvis.

collenchyma (kol-en'-kih-mah) Living cells with moderately but unevenly thickened primary cell walls; collenchyma cells help support the herbaceous plant body.

colon The region of the large intestine that extends from the cecum to the rectum.

colony An association of loosely connected cells or individuals of the same species.

commensalism (kuh-men'-sul-izm) A type of symbiosis in which one organism benefits and the other one is neither harmed nor helped. Compare with *mutualism* and *parasitism*.

commercial harvest The collection of commercially important organisms from the wild. Examples include the commercial harvest of parrots (for the pet trade) and cacti (for houseplants).

community An association of populations of different species living together in a defined habitat with some degree of interdependence. Compare with *ecosystem*.

community ecology The description and analysis of patterns and processes within the community.

compact bone Dense, hard bone tissue found mainly near the surfaces of a bone.

companion cell A cell in the phloem of flowering plants that governs loading and unloading sugar into the sieve tube element for translocation.

compass sense The sense of direction an animal requires to travel in a straight line toward a destination.

competition The interaction among two or more individuals that attempt to use the same essential resource, such as food, water, sunlight, or living space. See *interspecific* and *intraspecific competition*. See *interference* and *exploitation competition*.

competitive exclusion principle The concept that no two species with identical living requirements can occupy the same ecological niche indefinitely.

competitive inhibition Binding of a substance (the competitive inhibitor) to the active site of an enzyme, thus lowering the rate of the reaction catalyzed by the enzyme. Compare with *noncompetitive inhibition*.

competitive inhibitor See *competitive inhibition*.

complement A group of proteins in blood and other body fluids that are activated by an antigen-antibody complex and then destroy pathogens.

complementary base pairing The pairing of bases by hydrogen bond formation in double-stranded nucleic acids according to the base pairing rules: adenine pairs with thymine (in DNA) or uracil (in RNA), and guanine pairs with cytosine.

complementary DNA (cDNA) DNA synthesized by reverse transcriptase, using RNA as a template.

complete flower A flower that has all four parts: sepals, petals, stamens, and carpels. Compare with *incomplete flower*.

complete metamorphosis In insects, the transition during the life cycle from egg to larva, to pupa, and finally, to adult. Larvae have different forms and lifestyles than adults. Compare with *incomplete metamorphosis*.

compound eye An eye, such as that of an insect, consisting of many light-sensitive units called *ommatidia*.

concentration gradient A difference in the concentration of a substance from one point to another, as for example, across a cell membrane.

condensation reaction A reaction in which two monomers are combined covalently through the removal of the equivalent of a water molecule; also called *condensation synthesis*. Compare with *hydrolysis reaction*.

condensin Collective name for protein complex that binds DNA and forms it into coiled loops as part of the chromosome compaction process required for cell division.

cone (1) In botany, a reproductive structure in many gymnosperms that produces either microspores or megaspores. (2) In zoology, one of the conical photoreceptive cells of the retina that is particularly sensitive to bright light and, by distinguishing light of various wavelengths, mediates color vision. Compare with *rod*.

conidiophore (kah-nid'-e-o-for") A specialized hypha that bears conidia.

conidium (kah-nid'-e-um) (pl., *conidia*) An asexual spore that is usually formed at the tip of a specialized hypha called a *conidiophore*.

conifer (kon'-ih-fur) Any of a large phylum of gymnosperms that are woody trees and shrubs with needlelike, mostly evergreen leaves and with seeds in cones.

conjugation (kon"-jew-gay'-shun) (1) A sexual process in ciliate protists that involves exchange of haploid nuclei with another cell. (2) A mechanism for DNA exchange in bacteria that involves cell-to-cell contact.

connective tissue Animal tissue consisting mostly of an intercellular substance (fibers scattered through a matrix) in which the cells are embedded (e.g., bone).

conodonts Extinct, simple fishlike chordates with large eyes and tooth-like hooks; may have been early vertebrates.

conservation biology A multidisciplinary science that focuses on the study of how humans impact organisms and on the development of ways to protect biological diversity.

constitutive gene A gene that is constantly transcribed.

consumer See *heterotroph*.

consumption overpopulation A situation in which each individual in a human population consumes too large a share of resources; results in pollution, environmental degradation, and resource depletion. Compare with *people overpopulation*.

contest competition See *interference competition*.

continental drift The scientific theory that continents were once joined and later split and drifted apart.

contraception Any method used to intentionally prevent pregnancy.

contractile root (kun-trak'-til) A specialized type of root that contracts and pulls a bulb or corm deeper into the soil.

contractile vacuole A membrane-enclosed organelle found in certain freshwater protists, such as *Paramecium*; appears to have an osmoregulatory function.

control group In a scientific experiment, a group in which the experimental variable is kept constant. The control group, which is as closely matched to the experimental group as possible, provides a standard of comparison used to verify the results of the experiment. Compare with *experimental group*.

controlled burning Tool of ecological management in which the undergrowth and plant litter are deliberately burned under controlled conditions before they have accumulated to dangerous levels.

controlled mating A mating in which the genotypes of the parents are known.

convergence The functional arrangement of neurons in which a neuron receives signals from two or more presynaptic neurons. Compare with *divergence*.

convergent circuit (kun-vur'-jent) A neural pathway in which a postsynaptic neuron is controlled by signals coming from two or more presynaptic neurons. Compare with *divergent circuit*.

convergent evolution (kun-vur'-jent) The independent evolution of structural or functional similarity in two or more distantly related species, usually as a result of adaptations to similar environments.

convolutions The numerous folds of the cerebral cortex.

copy number variations (CNVs) Genetic variation among individuals in a population as measured by segments of DNA that have been gained or lost, compared to a reference genome.

coral bleaching The stress-induced loss of the symbiotic algae that inhabit coral cells.

coral reef Reef found in warm, shallow seas; built by coral which has solidified into layers of calcium carbonate (CaCO₃).

core angiosperms The clade to which most angiosperm species belong. Core angiosperms are divided into three subclades: magnoliids, monocots, and eudicots. Compare with *basal angiosperms*.

corepressor Substance that binds to a repressor protein, converting it to its active form, which is capable of preventing transcription.

Coriolis effect (kor'-e-o'-lis) The tendency of moving air or water to be deflected from its path to the right in the Northern Hemisphere and to the

left in the Southern Hemisphere. Caused by the direction of Earth's rotation.

cork cambium (kam'-bee-um) A lateral meristem that produces cork cells and cork parenchyma; cork cambium and the tissues it produces make up the *periderm* (outer bark) of a woody plant. Compare with *vascular cambium*.

cork cell A cell in the bark that is produced outwardly by the cork cambium; cork cells are dead at maturity and function for protection and reduction of water loss.

cork parenchyma (par-en'-kih-mah) One or more layers of parenchyma cells produced inwardly by the cork cambium.

corm A short, thickened underground stem specialized for food storage and asexual reproduction (e.g., crocus, gladiolus).

cornea (kor'-nee-ah) The transparent covering of an eye.

corolla (kor-ohl'-ah) Collectively, the petals of a flower.

coronary circulation The system of blood vessels that delivers blood to the heart muscle and returns blood from the heart muscle to the right atrium.

corpus callosum (kah-loh'-sum) In mammals, a large bundle of nerve fibers interconnecting the two cerebral hemispheres.

corpus luteum (loo'-tee'-um) The temporary endocrine tissue in the ovary that develops from the ruptured follicle after ovulation; secretes progesterone and estrogen.

cortex (kor'-teks) (1) The outer part of an organ, such as the cortex of the kidney. Compare with *medulla*. (2) The tissue between the epidermis and vascular tissue in the stems and roots of many herbaceous plants.

cortical reaction Process occurring after fertilization that prevents additional sperm from entering the egg; also known as the "slow block to polyspermy."

corticotropin-releasing factor (CRF) Secreted by the hypothalamus in response to stress; stimulates the anterior pituitary to secrete adrenocorticotrophic hormone (ACTH).

cortisol A steroid hormone, secreted by the adrenal cortex, that helps the body adjust to long-term stress; stimulates conversion of other nutrients to glucose in the liver, resulting in increased blood glucose concentration.

cosmopolitan species Species that have a nearly worldwide distribution and occur on more than one continent or throughout much of the ocean. Compare with *endemic species*.

cost-benefit analysis An analysis of the costs versus the benefits of a particular behavior; the costs and benefits are typically assessed in terms of direct fitness, an individual's reproductive success.

cotransport The active transport of a substance from a region of low concentration to a region of high concentration by coupling its transport to the transport of a substance down its concentration gradient.

cotyledon (kot'-uh-lee'-dun) The seed leaf of a plant embryo, which may contain food stored for germination.

crotylosaurs The first reptiles; also known as *stem reptiles*.

countercurrent exchange system A biological mechanism that enables maximum exchange

between two fluids. The two fluids must be flowing in opposite directions and have a concentration gradient between them.

coupled reactions A set of reactions in which an exergonic reaction provides the free energy required to drive an endergonic reaction; energy coupling generally occurs through a common intermediate.

courtship rituals Behaviors intended to attract or maintain the attention of a potential mate. A courtship ritual may be a signal that triggers nest building, ovulation, or mating.

covalent bond The chemical bond involving shared pairs of electrons; may be single, double, or triple (with one, two, or three shared pairs of electrons, respectively). Compare with *ionic bond* and *hydrogen bond*.

covalent compound A compound in which atoms are held together by covalent bonds; covalent compounds consist of molecules. Compare with *ionic compound*.

cranial nerves The 10 to 12 pairs of nerves in vertebrates that emerge directly from the brain; they transmit sensory information to the CNS; some cranial nerves transmit motor information from the CNS to effectors.

cranium The bony framework that protects the brain in vertebrates.

crash drive A gene drive method designed to increase the proportion of a lethal or sterile phenotype in successive generations, ultimately resulting in the extinction of a population.

crassulacean acid metabolism (CAM) pathway See *CAM plant*.

creatine phosphate An energy-storing compound in muscle cells.

crepuscular animals Animals most active during dusk, dawn, or both (e.g., fiddler crabs and mosquitoes). Compare with *diurnal animals* and *nocturnal animals*.

Cretaceous period See *Mesozoic era*.

cretinism (kree'-tin-izm) A chronic condition caused by lack of thyroid secretion during fetal development and early childhood; results in physical and intellectual disability if untreated.

cri du chat syndrome A human genetic disease caused by losing part of the short arm of chromosome 5 and characterized by intellectual disability, a cry that sounds like a kitten mewling, and death in infancy or childhood.

CRISPR Clusters of Regularly Interspersed Palindromic Repeats; a type of locus in the DNA of prokaryotes containing repeated sequences that code for guide RNAs that direct Cas endonuclease to cut certain DNA sequences; a prokaryotic defense against bacteriophages used in biotechnology as a basis for programmable editing of DNA in living cells.

cristae (kris'-tee) (sing., *crista*) Shelflike or fingerlike inward projections of the inner membrane of a mitochondrion.

cross bridges The connections between myosin and actin filaments in muscle fibers; formed by the binding of myosin heads to active sites on actin filaments.

crossing-over A process in which genetic material (DNA) is exchanged between paired, homologous chromosomes.

crustaceans Members of a subphylum that includes lobsters, crabs, shrimp, barnacles, and their relatives.

cryptic coloration Colors or markings that help some organisms hide from predators by blending into their physical surroundings. Compare with *aposematic coloration*.

cryptochrome A proteinaceous pigment that strongly absorbs blue light; implicated in resetting the biological clock in plants, fruit flies, and mice.

ctenophores (ten'-oh-forz) Phylum of marine animals (comb jellies) whose bodies consist of two layers of cells enclosing a gelatinous mass. The outer surface is covered with comblike rows of cilia, by which the animal moves.

culture Behavior common to a population, that is learned from members of the population, and transmitted from one generation to the next.

cupula In certain mechanoreceptors, the mass of gelatinous material that encloses the tips of stereocilia; secreted by the hair cells.

Cushing's syndrome Hormone disorder caused by overexposure to glucocorticoids; characterized by fat deposited around trunk, facial edema, and high blood glucose level, which causes *adrenal diabetes*. Long-term exposure may lead to permanent diabetes mellitus.

cuticle (kew'-tih-kl) (1) A noncell covering over the epidermis of the aerial parts of plants that reduces water loss; composed mainly of *cutin*, a waxy substance. (2) The outer covering of some animals, such as roundworms.

cyanobacteria (sy-an'-oh-bak-teer'-ee-uh) Prokaryotic photosynthetic microorganisms that possess chlorophyll and produce oxygen during photosynthesis.

cycad (sih'-kad) Any of a phylum of gymnosperms that live mainly in tropical and semitropical regions and have stout stems (to 20 m in height) and fernlike leaves.

cyclic adenosine monophosphate See *cyclic AMP*.

cyclic AMP (cAMP) A form of adenosine monophosphate in which the phosphate is part of a ring-shaped structure; acts as a regulatory molecule and second messenger in organisms ranging from bacteria to humans.

cyclic electron transport In photosynthesis, the cyclic flow of electrons through photosystem I; ATP is formed by chemiosmosis, but no photolysis of water occurs, and O₂ and NADPH are not produced. Compare with *noncyclic electron transport*.

cyclic GMP (cGMP) A form of guanosine monophosphate in which the phosphate is part of a ring-shaped structure; involved in certain cell signaling processes.

cyclic guanosine monophosphate See *cyclic GMP*.

cyclin-Cdk complex See *cyclins*.

cyclin-dependent kinases (Cdks) Protein kinases involved in controlling the cell cycle.

cyclins Regulatory proteins whose levels oscillate during the cell cycle; cyclins associate with cyclin-dependent kinases to form cyclin-Cdk complexes.

cystic fibrosis A genetic disease with an autosomal recessive inheritance pattern; characterized by secretion of abnormally thick mucus, particularly in the respiratory and digestive systems.

cytochromes (sy'-toh-kroh-mz) Iron-containing heme proteins of an electron transport system.

cytokines Signaling proteins that regulate interactions between cells in the immune system. Important groups include interferons, interleukins, tumor necrosis factors, and chemokines.

cytokinesis (sy'-toh-kih-nee'-sis) Stage of cell division in which the cytoplasm divides to form two daughter cells.

cytokinin (sy'-toh-ky'-nin) A plant hormone involved in various aspects of plant growth and development, such as cell division and delay of senescence.

cytoplasm The plasma membrane and cell contents with the exception of the nucleus.

cytosine A nitrogenous pyrimidine base that is a component of nucleic acids.

cytoskeleton The dynamic internal network of protein fibers that includes microfilaments, intermediate filaments, and microtubules.

cytosol The fluid component of the cytoplasm in which the organelles are suspended.

cytotoxic T cell See *T cytotoxic cell*.

dalton See *atomic mass unit (amu)*.

day-neutral plant A plant whose flowering is not controlled by variations in day length that occur with changing seasons. Compare with *long-day*, *short-day*, and *intermediate-day plants*.

deamination (dee-am-ih-nay'-shun) The removal of an amino group (—NH₂) from an amino acid or other organic compound.

decapods Lobsters, crabs, shrimp, crayfish, and other species assigned to order Decapoda, the largest order of crustaceans.

decarboxylation A reaction in which a molecule of CO₂ is removed from a carboxyl group of an organic acid.

deciduous A term describing a plant that sheds leaves or other structures at regular intervals (e.g., during autumn). Compare with *evergreen*.

declarative memory Factual knowledge of people, places, or objects; requires conscious recall of the information.

decomposers Microbial heterotrophs that break down dead organic material and use the decomposition products as a source of energy. Also called *saprotrophs* or *saprobies*.

deductive reasoning The reasoning that operates from generalities to specifics and can make relationships among data more apparent. Compare with *inductive reasoning*. See *hypothetico-deductive approach*.

deforestation The temporary or permanent removal of forest for agriculture or other uses.

dehydrogenation (dee-hy'-dro-jen-ay'-shun) A form of oxidation in which hydrogen atoms are removed from a molecule.

deletion (1) A chromosome abnormality in which part of a chromosome is missing (e.g., cri du chat syndrome). (2) The loss of one or more base pairs from DNA, which can result in a frameshift mutation.

demographics The science that deals with human population statistics, such as size, density, and distribution.

denature (dee-nay'-ture) To alter the physical properties and three-dimensional structure of a protein, nucleic acid, or other macromolecule by treating it with excess heat, strong acids, or strong bases.

dendrites (den'-dritez) Branches of a neuron that receive and conduct nerve impulses toward the cell body. Compare with *axon*.

dendritic cells A set of immune cells present in many tissues that capture antigens and present them to T cells.

dendrochronology (den'-dro-kruh-naal'-uh-gee) A method of dating that uses the annual rings of trees.

denitrification (dee-nie'-tra-fuh-kay'-shun) The conversion of nitrate (NO₃⁻) to nitrogen gas (N₂) by certain bacteria (denitrifying bacteria) in the soil; part of the nitrogen cycle.

dense connective tissue A type of tissue that may be irregular, as in the dermis of the skin, or regular, as in tendons.

density-dependent factor An environmental factor whose effects on a population change as population density changes; tends to retard population growth as population density increases and enhance population growth as population density decreases. Compare with *density-independent factor*.

density gradient centrifugation Procedure in which cell components are placed in a layer on top of a density gradient, usually a sucrose solution and water. Cell structures migrate during centrifugation, forming a band at the position in the gradient where their own density equals that of the sucrose solution.

density-independent factor An environmental factor that affects the size of a population but is not influenced by changes in population density. Compare with *density-dependent factor*.

deoxyribonucleic acid (DNA) Double-stranded nucleic acid; contains genetic information coded in specific sequences of its constituent nucleotides.

deoxyribose Pentose sugar lacking a hydroxyl (—OH) group on carbon-2'; a constituent of DNA.

depolarization (dee-pol'-ar-ih-zay'-shun) A decrease in the charge difference across a plasma membrane; may result in an action potential in a neuron or muscle cell.

deposit feeder Animal that consumes nutrients by ingesting soil or sediments.

derived characters See *shared derived characters*.

dermal tissue system The tissue that forms the outer covering over a plant; the epidermis or periderm.

dermis (dur'-mis) The layer of dense connective tissue beneath the epidermis in the skin of vertebrates.

desert A temperate or tropical biome in which lack of precipitation limits plant growth.

desertification The degradation of once-fertile land into nonproductive desert; caused partly by soil erosion, deforestation, and overgrazing by domestic animals.

desmosomes (dez'-moh-sohmz) Buttonlike plaques, present on two opposing cell surfaces, that hold the cells together by means of protein filaments that span the intercellular space.

determinate cleavage Type of cleavage, characteristic of protostomes, in which the fate of each cell is determined when the cell is produced. Compare with *indeterminate cleavage*.

determinate growth Growth of limited duration, as for example, in flowers and leaves. Compare with *indeterminate growth*.

determination The developmental process by which one or more cells become progressively committed to a particular fate. Determination is a series of molecular events usually leading to differentiation. Also called *cell determination*.

detritivore (duh-try'-tuh-vore) An organism, such as an earthworm or crab, that consumes fragments of freshly dead or decomposing organisms; also called *detritus feeder*.

detritus (duh-try'-tus) Organic debris from decomposing organisms.

detritus feeder See *detritivore*.

deuteromycetes (doo'-ter-o-my'-seats) An artificial grouping of fungi characterized by the absence of sexual reproduction but usually having other traits similar to ascomycetes; also called *imperfect fungi*.

deuterostomes (doo'-ter-oh-stomes) Animals that belong to the Deuterostomia, one of the major animal clades; include the echinoderms and chordates. Compare with *protostomes*.

development All the progressive changes that take place throughout the life of an organism.

developmental genetics Study of how genes and gene expression affect the differentiation of cells and the development of an organism.

Devonian period See *Paleozoic era*.

diabetes mellitus (mel'-i-tus) The most common endocrine disorder. In type 1 diabetes, there is a marked decrease in the number of beta cells in the pancreas, resulting in insulin deficiency. In the more common type 2 diabetes, insulin receptors on target cells do not bind with insulin (insulin resistance).

diacylglycerol (DAG) (di''-as-il-glis'-er-ol) A lipid consisting of glycerol combined chemically with two fatty acids; also called *diglyceride*. Compare with *monoacylglycerol* and *triacylglycerol*.

dialysis The diffusion of certain solutes across a selectively permeable membrane.

diaphragm In mammals, the muscular floor of the chest cavity; contracts during inhalation, expanding the chest cavity.

diapsids (di-ap'-sids) Members of a clade of amniotes in which the skull has two pairs of temporal openings; includes all extant reptilian groups (including birds) as well as most extinct reptiles. Compare with *synapsids*.

diastole (di-ass'-toh-lee) Phase of the cardiac cycle in which the heart is relaxed. Compare with *systole*.

diatom (die'-eh-tom") A usually unicellular stramenopile alga that is covered by an ornate, siliceous shell consisting of two overlapping halves; an important component of plankton in both marine and fresh waters.

dichotomous branching (di-kaut'-uh-mus) In botany, a type of branching in which one part always divides into two more or less equal parts.

diencephalon See *forebrain*.

differential centrifugation Separation of cell particles according to their mass, size, or density. In differential centrifugation, the supernatant is spun at successively higher revolutions per minute.

differential gene expression The expression of different subsets of genes at different times and in different cells during development.

differentiated cell A specialized cell; carries out unique activities, expresses a specific set of proteins, and usually has a recognizable appearance.

differentiation (dif''-ah-ren-she-ay'-shun) Development toward a more mature state; a process changing a young, relatively unspecialized cell to a more specialized cell. Also called *cell differentiation*.

diffusion The net movement of particles (atoms, molecules, or ions) from a region of higher concentration of that type of particle to a region of lower concentration (i.e., down a concentration gradient), resulting from random motion; also called *simple diffusion*. Compare with *facilitated diffusion* and *active transport*.

digestion The breakdown of food to small molecules.

diglyceride See *diacylglycerol*.

dihybrid cross (dy-hy'-brid) A genetic cross that takes into account the behavior of alleles of two loci. Compare with *monohybrid cross*.

dikaryotic (dy-kare-ee-ot'-ik) Condition of having two nuclei per cell (i.e., $n + n$), characteristic of certain fungal hyphae. Compare with *monokaryotic*.

dimer An association of two monomers (e.g., a disaccharide or a dipeptide).

dinoflagellate (dy''-noh-flaj'-eh-late) A unicellular, biflagellate, typically marine protist that is an important component of plankton; usually photosynthetic.

dioecious (dy-ee'-shus) Having male and female reproductive structures on separate plants; compare with *monoecious*.

dipeptide See *peptide*.

diploblastic (dip-lo-blas'-tik) Animal body plan in which there are only two embryonic tissue layers, the ectoderm and endoderm. Compare with *triploblastic*.

diploid (dip'-loyd) The condition of having two sets of chromosomes per nucleus. Compare with *haploid* and *polyploid*.

diplomonads Small, mostly parasitic excavates with one or two nuclei, no functional mitochondria, and one to four flagella.

directed evolution See *in vitro evolution*.

direct fitness An individual's reproductive success, measured by the number of viable offspring it produces. Compare with *inclusive fitness*.

directional selection The gradual replacement of one phenotype with another because of environmental change that favors phenotypes at one of the extremes of the normal distribution. Compare with *stabilizing selection* and *disruptive selection*.

disaccharide (dy-sak'-ah-ride) A sugar produced by covalently linking two monosaccharides (e.g., maltose or sucrose).

disomy The normal condition in which both members of a chromosome pair are present in a diploid cell or organism. Compare with *monosomy* and *trisomy*.

dispersal The movement of individuals among populations. See *immigration* and *emigration*.

dispersion The pattern of distribution in space of the individuals of a population relative to

their neighbors; see *clumped dispersion*, *random dispersion*, and *uniform dispersion*.

disruptive selection A special type of directional selection in which changes in the environment favor two or more variant phenotypes at the expense of the mean. Compare with *stabilizing selection* and *directional selection*.

distal Remote; farther from the point of reference. Compare with *proximal*.

distal convoluted tubule The part of the renal tubule that extends from the loop of Henle to the collecting duct. Compare with *proximal convoluted tubule*.

disturbance In ecology, any event that disrupts community or population structure.

diurnal animals Animals most active during the day (e.g., pigeons). Compare with *crepuscular animals* and *nocturnal animals*.

divergence The functional arrangement of neurons in which a neuron sends signals to two or more postsynaptic neurons. Compare with *convergence*.

divergent circuit A neural pathway in which a presynaptic neuron stimulates many postsynaptic neurons. Compare with *convergent circuit*.

diving reflex A group of physiological mechanisms, such as decrease in metabolic rate, that are activated when a mammal dives to its limit.

dizygotic twins Twins that arise from the separate fertilization of two eggs; commonly known as *fraternal twins*. Compare with *monozygotic twins*.

DNA See *deoxyribonucleic acid*.

DNA chip See *DNA microarray*.

DNA cloning The process of selectively amplifying DNA sequences so their structure and function can be studied.

DNA fingerprinting The analysis of DNA fragments extracted from an individual; the resulting pattern is unique to that individual.

DNA ligase Enzyme that catalyzes the joining of the 5' and 3' ends of two DNA fragments; essential in DNA replication and used in recombinant DNA technology.

DNA methylation A process in which gene inactivation is perpetuated by enzymes that add methyl groups to DNA.

DNA microarray A diagnostic test involving thousands of DNA molecules placed on a glass slide or chip.

DNA polymerases Family of enzymes that catalyze the synthesis of DNA from a DNA template by adding nucleotides to a growing 3' end.

DNA primase Enzyme that begins the process of DNA replication by synthesizing a short RNA segment complementary to the DNA template strand; this RNA strand is subsequently degraded and replaced with DNA.

DNA probe A labeled single-stranded DNA fragment used to detect a gene of interest in a hybridization experiment.

DNA provirus Double-stranded DNA molecule that is an intermediate in the life cycle of an RNA tumor virus (retrovirus).

DNA replication The process by which DNA is duplicated; ordinarily a semiconservative process in which a double helix gives rise to two double helices, each with an "old" strand and a newly synthesized strand.

DNA sequencing Procedure by which the sequence of nucleotides in DNA is determined.

domain (1) A structural and functional region of a protein. (2) The broadest taxonomic category; each domain includes one or more kingdoms.

dominance hierarchy A linear “pecking order” into which animals in a population may organize according to status; regulates aggressive behavior within the population.

dominant allele (al-leel') An allele that is always expressed when it is present, regardless of whether it is homozygous or heterozygous. Compare with *recessive allele*.

dominant species In a community, a species that as a result of its large biomass or abundance exerts a major influence on the distribution of populations of other species.

dopamine A neurotransmitter of the biogenic amine group; important in motor function.

dormancy A temporary period of arrested growth in plants or plant parts such as spores, seeds, bulbs, and buds.

dorsal (dor'-sl) Toward the uppermost surface or back of an animal. Compare with *ventral*.

dosage compensation Genetic mechanism by which the expression of X-linked genes is made equivalent in XX females and XY males; in mammals this is accomplished by rendering all but one X chromosome inactive.

double fertilization A process in the flowering plant life cycle in which there are two fertilizations; one fertilization results in formation of a zygote, whereas the second results in formation of endosperm.

double helix The structure of DNA, which consists of two antiparallel polynucleotide chains twisted around each other.

doubling time The amount of time it takes for a population to double in size, assuming that its current rate of increase does not change. Doubling time can be estimated by dividing 70 by the rate of increase (percent increase per unit of time).

Down syndrome An inherited condition in which individuals have abnormalities of the face, eyelids, tongue, and other parts of the body and exhibit physical and intellectual disability; usually results from trisomy of chromosome 21.

drupe (droop) A simple, fleshy fruit in which the inner wall of the fruit is a hard stone (e.g., peach, cherry).

duodenum (doo"-o-dee'-num) The portion of the small intestine into which the contents of the stomach first enter.

duplication An abnormality in which a set of chromosomes contains more than one copy of a particular chromosomal segment; the translocation form of Down syndrome is an example.

dura mater The tough, outer meningeal layer that covers and protects the brain and spinal cord. Also see *arachnoid* and *pia mater*.

dynamic equilibrium The condition of a chemical reaction when the rate of change in one direction is exactly the same as the rate of change in the opposite direction (i.e., the concentrations of the reactants and products are not changing), and the difference in free energy between reactants and products is zero.

dynein See *microtubule-associated proteins* (MAPs).

ecdysis Molting; shedding outer skin; common process in insects, crustaceans, and snakes.

ecdysone (ek'-dih-sone) See *molting hormone*.

Ecdysozoa A branch of the protostomes that includes animals that molt, such as the rotifers, nematodes, and arthropods.

echinoderms (eh-kine'-oh-derms) Phylum of spiny-skinned marine deuterostome invertebrates characterized by a water vascular system and tube feet; include sea stars, sea urchins, and sea cucumbers.

echolocation Determination of the position of objects by detecting echoes of high-pitched sounds emitted by an animal; a type of sensory system used by bats and dolphins.

ecological niche See *niche*.

ecological pyramid A graphical representation of the relative energy value at each trophic level. See *pyramid of biomass* and *pyramid of energy*.

ecological succession See *succession*.

ecology (ee-kol'-uh-jee) A discipline of biology that studies the interrelations among living things and their environments.

ecosystem (ee'-koh-sis-tem) The interacting system that encompasses a community and its nonliving, physical environment. Compare with *community*.

ecosystem diversity Variety of ecosystems found on Earth such as forests, prairies, deserts, lakes, coastal estuaries, and coral reefs.

ecosystem ecology A subfield of ecology that studies energy flow and the cycling of chemicals among the interacting biotic and abiotic parts of an ecosystem.

ecosystem management A conservation focus that emphasizes restoring and maintaining ecosystem quality rather than the conservation of individual species.

ecosystem services Important environmental services, such as clean air to breathe, clean water to drink, and fertile soil in which to grow crops, that ecosystems provide.

ecotone The transition zone where two communities meet and intergrade.

ectoderm (ek'-toh-derm) The outer germ layer of the early embryo; gives rise to the skin and nervous system. Compare with *mesoderm* and *endoderm*.

ectomycorrhizal fungi See *mycorrhizae*.

ectoparasite A tick or other parasite that lives outside its host's body. Compare with *endoparasite*.

ectotherm An animal whose temperature fluctuates with that of the environment; may use behavioral adaptations to regulate temperature; sometimes referred to as *cold-blooded*. Compare with *endotherm*.

edge effect The ecological phenomenon in which ecotones between adjacent communities often contain a greater number of species or greater population densities of certain species than either adjacent community.

Ediacaran period (ee-dee-ack'-uh-ran") The last (most recent) period of the Proterozoic eon, from 635 million to 541 million years ago; named for early animal fossils found in the Ediacara Hills in South Australia.

effector (1) A muscle or gland that contracts or secretes in direct response to nerve impulses. (2) In homeostasis, an organ or process that helps restore a steady state.

efferent (ef'-fur-ent) Leading away from some point of reference. Compare with *afferent*.

efferent arteriole In the mammalian kidney, an arteriole that conducts blood away from a glomerulus. Compare with *afferent arteriole*.

efferent neurons Neurons that transmit action potentials from the brain or spinal cord to muscles or glands. Compare with *afferent neurons*.

ejaculation (ee-jak"-yoo-lay'-shun) A sudden expulsion, as in the ejection of semen from the penis.

ejaculatory duct A short duct that passes through the prostate gland and opens into the urethra; receives semen from the vas deferens.

electrical synapse A junction between two neurons in which an action potential in the presynaptic neuron spreads directly to the postsynaptic neuron by way of gap junctions. Compare with *chemical synapse*.

electrochemical gradient A difference in charge and chemical concentration existing between two regions.

electrolyte A substance that dissociates into ions when dissolved in water; the resulting solution can conduct an electric current.

electron A particle with one unit of negative charge and negligible mass, located outside the atomic nucleus. Compare with *neutron* and *proton*.

electron configuration The arrangement of electrons around the atom. In a Bohr model, the electron configuration is depicted as a series of concentric circles.

electronegativity A measure of an atom's attraction for electrons.

electron microscope A microscope capable of producing high-resolution, highly magnified images through the use of an electron beam (rather than light). Transmission electron microscopes (TEMs) produce images of thin sections; scanning electron microscopes (SEMs) produce images of surfaces.

electron shell Group of orbitals of electrons with similar energies.

electron transport system A series of redox reactions during which hydrogens or their electrons are passed along an electron transport chain from one acceptor molecule to another, with the release of energy.

electron transport chain See *electron transport system*.

electrophoresis, gel See *gel electrophoresis*.

electroreceptor A receptor that responds to electrical stimuli.

element A substance that cannot be changed to a simpler substance by a normal chemical reaction.

elimination Ejection of undigested food from the body. Compare with *excretion*.

elongation (in protein synthesis) Cyclic process by which amino acids are added one by one to a growing polypeptide chain. See *initiation* and *termination*.

El Niño–Southern Oscillation (ENSO) (el nee'-nyo) A recurring climatic phenomenon that involves a surge of warm water in the Pacific Ocean and unusual weather patterns elsewhere in the world.

embryo (em'-bree-oh) (1) A young organism before it emerges from the egg, seed, or body of its mother. (2) Developing human until the end of the second month, after which it is referred to as a fetus. (3) In plants, the young sporophyte produced following fertilization and subsequent development of the zygote.

embryonic stem cell (ES cell) A pluripotent stem cell derived from an early stage embryo.

embryo sac The female gametophyte generation in flowering plants.

embryo transfer See *host mothering*.

emergent properties Characteristics of an object, process, or behavior that could not be predicted from its component parts; emergent properties can be identified at each level as we move up the hierarchy of biological organization.

emerging diseases Diseases new to the human population; often appear suddenly. Compare with *re-emerging diseases*.

emigration The movement of individuals out of a population. Compare with *immigration*.

enantiomers (en-an'-tee-oh-merz) Two isomeric chemical compounds that are mirror images.

Encode Project (ENCyclopedia of DNA Elements) An international collaborative project to determine all the functional elements within the human genome. Initial results published in 2012 showed that at least 80% of non-protein-coding human DNA has biochemical functions.

3' end End of a nucleic acid strand that has a 3' carbon of deoxyribose (DNA) or ribose (RNA) attached to a hydroxyl group. Compare with *5' end*.

5' end End of a nucleic acid strand that has a 5' carbon of deoxyribose (DNA) or ribose (RNA) attached to a phosphate group. Compare with *3' end*.

endangered species A species whose numbers are so severely reduced that it is in imminent danger of extinction throughout all or part of its range. Compare with *threatened species*.

endemic species Localized, native species that are not found anywhere else in the world. Compare with *cosmopolitan species*.

endergonic reaction (end'-er-gon'-ik) A nonspontaneous reaction; a reaction requiring a net input of free energy. Compare with *exergonic reaction*.

endocrine gland (en'-doh-crin) A gland that secretes hormones directly into the blood or tissue fluid instead of into ducts. Compare with *exocrine gland*.

endocrine system The body system that helps regulate metabolic activities; consists of ductless glands and tissues that secrete hormones.

endocrinology Study of the endocrine system and endocrine activity, including the production and actions of chemical messengers produced by organs, tissues, and cells.

endocytosis (en'-doh-sy-toh'-sis) The active transport of substances into the cell by the formation of invaginated regions of the plasma membrane that pinch off and become cytoplasmic vesicles. Includes *phagocytosis*, *pinocytosis*, and *receptor-mediated endocytosis*. Compare with *exocytosis*.

endoderm (en'-doh-derm) The inner germ layer of the early embryo; becomes the lining of the digestive tract and the structures that develop from

the digestive tract—liver, lungs, and pancreas. Compare with *ectoderm* and *mesoderm*.

endodermis (en"-doh-der'-mis) The innermost layer of the plant root cortex. Endodermal cells have a waterproof Casparian strip around their radial and transverse walls that ensures that water and minerals enter the xylem only by passing through the endoderm cells.

endolymph (en'-doh-limf) The fluid of the membranous labyrinth and cochlear duct of the ear.

endomembrane system The group of membranous structures in eukaryotic cells that interact through direct connections by vesicles; includes the endoplasmic reticulum, outer membrane of the nuclear envelope, Golgi complex, lysosomes, and the plasma membrane; also called *internal membrane system*.

endometrium (en"-doh-mee'-tree-um) The uterine lining.

endomycorrhizal fungi See *mycorrhizae*.

endoparasite A parasite such as a tapeworm that lives within the host. Compare with *ectoparasite*.

endoplasmic reticulum (ER) (en'-doh-plaz"-mik reh-tik'-yoo-lum) An interconnected network of internal membranes in eukaryotic cells enclosing a compartment, the ER lumen. Rough ER has ribosomes attached to the cytosolic surface; smooth ER, a site of lipid biosynthesis, lacks ribosomes.

endorphins (en-dor'-finz) Neuropeptides that block pain signals; released by certain neurons in the CNS.

endoskeleton (en"-doh-skel'-eh-ton) Bony and/or cartilaginous structures within the body that provide support. Compare with *exoskeleton*.

endosperm (en'-doh-sperm) The 3*n* nutritive tissue that is formed at some point in the development of all angiosperm seeds.

endospore A resting cell formed by certain bacteria; highly resistant to heat, radiation, and disinfectants.

endostyle A shared derived character of chordates; a groove in the floor of the pharynx that secretes mucus and traps food particles in sea water passing through the pharynx. In vertebrates, the thyroid gland is derived from the endostyle.

endosymbiont (en"-doh-sim'-bee-ont) An organism that lives inside the body or a cell of another kind of organism. Endosymbionts may benefit their host (mutualism) or harm their host (parasitism).

endosymbiosis Type of symbiosis in which one organism lives inside another. See *endosymbiont*.

endothelium (en-doh-theel'-ee-um) The tissue that lines the cavities of the heart, blood vessels, and lymph vessels.

endotherm (en'-doh-therm) An animal that uses metabolic energy to maintain a constant body temperature despite variations in environmental temperature (e.g., birds and mammals). Compare with *ectotherm*.

endotoxin A poisonous substance in the cell walls of gram-negative bacteria. Compare with *exotoxin*.

end product inhibition See *feedback inhibition*.

energy The capacity to do work; expressed in kilojoules or kilocalories.

energy flow Passage of energy in a one-way direction through an ecosystem.

energy of activation See *activation energy*.

enhanced greenhouse effect See *greenhouse effect*.

enhancers Regulatory DNA sequences that enhance gene transcription; can be located long distances away from the actual coding regions of a gene.

enkephalins (en-kef'-ah-linz) Neuropeptides that block pain signals; released by certain neurons in the CNS.

enthalpy The total potential energy of a system; sometimes referred to as the "heat content of the system."

entropy (en'-trop-ee) Disorderliness; a quantitative measure of the amount of the random, disordered energy that is unavailable to do work.

environmental resistance Unfavorable environmental conditions, such as crowding, that prevent organisms from reproducing indefinitely at their intrinsic rate of increase.

environmental sustainability The ability to meet humanity's current needs without compromising the ability of future generations to meet their needs.

enzyme (en'-zime) An organic catalyst (usually a protein) that accelerates a specific chemical reaction by lowering the activation energy required for that reaction.

enzyme-linked receptors Transmembrane proteins with a hormone-binding site outside the cell and an enzyme site inside the cell.

enzyme-substrate complex The temporary association between enzyme and substrate that forms during the course of a catalyzed reaction; also called *ES complex*.

eon The largest division of the geologic time scale; eons are divided into eras.

eosinophil (ee-oh-sin'-oh-fil) A type of white blood cell whose cytoplasmic granules absorb acidic stains; functions in parasitic infestations and allergic reactions.

ependymal cells Ciliated cells that line internal cavities of CNS; help produce and circulate cerebrospinal fluid.

epidermis (ep-ih-dur'-mis) (1) An outer layer of cells that covers the body of plants and functions primarily for protection. (2) The outer layer of vertebrate skin.

epididymis (ep-ih-did'-ih-mis) (pl., *epididymides*) A coiled tube that receives sperm from the testis and conveys it to the vas deferens.

epigenetic inheritance Inheritance that involves changes in how a gene is expressed without any change in that gene's nucleotide sequence.

epigenome The set of chemical modifications to the genome that do not alter the DNA base sequence, but alter gene expression by modifying the structure of the chromosomes.

epiglottis A thin, flexible structure that guards the entrance to the larynx, preventing food from entering the airway during swallowing.

epinephrine (ep-ih-nef'-rin) Hormone produced by the adrenal medulla; stimulates the sympathetic nervous system.

epiphyte Plant that grows attached to another plant.

epistasis (ep-ih-sta'-sis) Condition in which certain alleles of one locus alter the expression of alleles of a different locus.

epithelial tissue (ep-ih-theel'-ee-al) The type of animal tissue that covers body surfaces, lines body cavities, and forms glands; also called *epithelium*.

epoch The smallest unit of geologic time; a subdivision of a period.

equilibrium See *dynamic equilibrium*, *genetic equilibrium*, and *punctuated equilibrium*.

equilibrium potential The membrane potential at which the flow of a particular type of ion inward (due to the electrical gradient) equals the flow of that ion outward (because of the concentration gradient).

era An interval of geologic time that is a subdivision of an eon; eras are divided into periods.

erythroblastosis fetalis (eh-rith'-row-blas-toe'-sis fi-tal'-is) Serious condition in which Rh⁺ red blood cells (which bear antigen D) of a fetus are destroyed by maternal anti-D antibodies.

erythrocyte (eh-rith'-row-site) A vertebrate red blood cell; contains hemoglobin, which transports oxygen. Compare with *leukocyte*.

erythropoietin (eh-rith'-row-poy'-ih-tin) A peptide hormone secreted mainly by kidney cells; stimulates red blood cell production.

ES complex See *enzyme-substrate complex*.

esophagus (e-sof'-ah-gus) The part of the digestive tract that conducts food from the pharynx to the stomach.

essential amino acid An amino acid that must be provided in the diet because the body cannot make it or cannot make it in sufficient quantities to meet nutritional needs.

essential nutrient A nutrient that must be provided in the diet because the body cannot make it or cannot make it in sufficient quantities to meet nutritional needs (e.g., essential amino acids and essential fatty acids).

ester linkage Covalent linkage formed by the reaction of a carboxyl group and a hydroxyl group, with the removal of the equivalent of a water molecule; the linkage includes an oxygen atom bonded to a carbonyl group.

estivation A state of torpor caused by lack of food or water during periods of high temperature. Compare with *hibernation*.

estrogens (es'-troh-jenz) Female sex hormones produced by the ovary; promote the development and maintenance of female reproductive structures and of secondary sex characteristics.

estuary (es'-choo-wear-ee) A coastal body of water that connects to an ocean, in which fresh water from the land mixes with salt water.

ethology (ee-thol'-oh-jee) The study of animal behavior under natural conditions from the point of view of adaptation.

ethyl alcohol A 2-carbon alcohol.

ethylene (eth'-ih-leen) A gaseous plant hormone involved in various aspects of plant growth and development, such as leaf abscission and fruit ripening.

euchromatin (yoo-croh'-mah-tin) A loosely coiled chromatin that is generally capable of transcription. Compare with *heterochromatin*.

eudicot (yoo-dy'-kot) One of the two clades of flowering plants; eudicot seeds contain two cotyledons, or seed leaves. Compare with *monocot*.

euglenoids (yoo-gee'-noidz) A group of mostly freshwater unicellular excavates that move by means of an anterior flagellum and are usually photosynthetic.

Eukarya (yoo'-kar'-ee-ah) The domain that includes all eukaryotes: protists, fungi, plants, and animals.

eukaryote (yoo'-kar'-ee-ote) An organism whose cells have nuclei and other membrane-enclosed organelles. Compare with *prokaryote*.

eukaryotic cell See *eukaryote*.

Eumetazoa (yu'-met-uh-zo'-ah) A clade of animals with true tissues; almost all animals except sponges are eumetazoans. Compare with *Parazoa*.

euphotic zone The upper reaches of the ocean, in which enough light penetrates to support photosynthesis.

eustachian tube (yoo-stay'-shee-un) The auditory tube passing between the middle-ear cavity and the pharynx in vertebrates; permits the equalization of pressure on the tympanic membrane.

eutherians A clade of mammals characterized by a well-developed placenta; the young are more developed at birth than are marsupials.

eutrophic lake A lake enriched with nutrients such as nitrate and phosphate and consequently overgrown with plants or algae.

evergreen A plant that sheds leaves over a long period, so some leaves are always present. Compare with *deciduous*.

Evo Devo The study of the evolution of the genetic control of development.

evolution Any cumulative genetic changes in a population from generation to generation. Evolution leads to differences in populations and explains the origin of all the organisms that exist today or have ever existed.

evolutionary species concept See *phylogenetic species concept*.

evolutionary systematics An approach to classification that considers both evolutionary relationships and the extent of divergence that has occurred since a group branched from an ancestral group. Compare with *cladistics* and *phenetics*.

excavates Flagellated unicellular protists, many of which have a deep (excavated) oral groove; include diplomonds, parabasilids, and euglenoids.

excitatory postsynaptic potential (EPSP) A change in membrane potential that brings a neuron closer to the firing level. Compare with *inhibitory postsynaptic potential (IPSP)*.

excretion (ek-skree'-shun) The discharge from the body of a waste product of metabolism (not to be confused with the elimination of undigested food materials). Compare with *elimination*.

excretory system The body system in animals that functions in osmoregulation and in the discharge of metabolic wastes.

exergonic reaction (ex'-er-gon'-ik) A reaction characterized by a release of free energy. Also called *spontaneous reaction*. Compare with *endergonic reaction*.

exocrine gland (ex'-oh-crin) A gland that excretes its products through a duct that opens onto a free surface, such as the skin (e.g., sweat glands). Compare with *endocrine gland*.

exocytosis (ex'-oh-sy-toh'-sis) The active transport of materials out of the cell by fusion of cytoplasmic vesicles with the plasma membrane. Compare with *endocytosis*.

exon (1) A protein-coding region of a eukaryotic gene. (2) The mRNA transcribed from such a region. Compare with *intron*.

exoskeleton (ex'-oh-skel'-eh-ton) An external skeleton, such as the shell of mollusks or outer covering of arthropods; provides protection and sites of attachment for muscles. Compare with *endoskeleton*.

exotoxin A poisonous substance released by certain bacteria. Compare with *endotoxin*.

experimental group In a scientific experiment, a group in which the experimental variable is manipulated. Compare with *control group*.

exploitation competition Intraspecific competition in which all the individuals in a population "share" the limited resource equally so that at high population densities none of them obtains an adequate amount. Also called *scramble competition*. Compare with *interference competition*.

exponential population growth The accelerating population growth that occurs when optimal conditions allow a constant per capita growth rate. Compare with *logistic population growth*.

ex situ conservation Conservation efforts that involve conserving individual species in human-controlled settings, such as zoos. Compare with *in situ conservation*.

external fertilization The process in which gametes meet outside the body, typically when females release eggs and males release sperm into the surrounding water; occurs in most aquatic invertebrates, bony fishes, and amphibians. Compare with *internal fertilization*.

exteroceptor (ex'-tur-oh-sep'-tor) One of the sense organs that receives sensory stimuli from the outside world, such as the eyes or touch receptors. Compare with *interoceptor*.

extinction The elimination of a species; occurs when the last individual member of a species dies; see *background extinction* and *mass extinction*.

extracellular matrix (ECM) A network of proteins and carbohydrates that surrounds many animal cells.

extraembryonic membranes Multicellular membranous structures that develop from the germ layers of a terrestrial vertebrate embryo but are not part of the embryo itself. See *chorion*, *amnion*, *allantois*, and *yolk sac*.

extreme halophiles Certain types of archaea, and few types of bacteria and protists, that inhabit environments with very high salt concentrations.

extreme thermophiles Certain types of archaea that require a very high temperature or very low temperature for growth.

F₁ generation (first filial generation) The first generation of hybrid offspring resulting from a cross between parents from two different true-breeding lines.

F₂ generation (second filial generation) The offspring of the F₁ generation.

facilitated diffusion The passive transport of ions or molecules by a specific carrier protein in a membrane. As in simple diffusion, net transport is down a concentration gradient, and no additional energy has to be supplied. Compare with *diffusion* and *active transport*.

facilitation In ecology, a situation in which one species has a positive effect on other species in the community, for example, by enhancing the local environment.

facultative anaerobe An organism capable of carrying out aerobic cellular respiration but able to switch to fermentation when oxygen is unavailable (e.g., yeast). Compare with *obligate anaerobe*.

FAD/FADH₂ Oxidized and reduced forms, respectively, of flavin adenine dinucleotide, a coenzyme that transfers electrons (as hydrogen) in metabolism, including cellular respiration.

fallopian tube See *oviduct*.

fall turnover Mixing of temperate lake waters in autumn, caused by falling temperatures, in which surface water sinks to the bottom and bottom water rises to the surface. Compare with *spring turnover*.

family A taxonomic category made up of related genera.

fast-glycolytic fibers White muscle fibers that generate a lot of power for a brief period; they contract rapidly, fatigue quickly, and obtain most of their ATP from glycolysis. Compare with *fast-oxidative fibers* and *slow-oxidative fibers*.

fast-oxidative fibers Muscle fibers specialized for rapid response; they contract quickly, have an intermediate rate of fatigue, and obtain most of their ATP from aerobic respiration. Compare with *slow-oxidative fibers* and *fast-glycolytic fibers*.

fatty acid A lipid that is an organic acid containing a long hydrocarbon chain, with no double bonds (saturated fatty acid), one double bond (monounsaturated fatty acid), or two or more double bonds (polyunsaturated fatty acid); components of triacylglycerols and phospholipids, as well as monoacylglycerols and diacylglycerols.

fatty acid derivatives Prostaglandins, juvenile hormones of insects, and other compounds derived from fatty acids.

fecundity The potential capacity of an individual to produce offspring.

feedback inhibition A type of enzyme regulation in which the accumulation of the product of a reaction inhibits an earlier reaction in the sequence; also known as *end product inhibition*.

fermentation An anaerobic process by which ATP is produced by a series of redox reactions in which organic compounds serve both as electron donors and terminal electron acceptors.

fern One of a phylum of seedless vascular plants that reproduce by spores produced in sporangia; ferns undergo an alternation of generations between the dominant sporophyte and the gametophyte (prothallus).

fertilization The fusion of two *n* gametes; results in the formation of a 2*n* zygote. Compare with *double fertilization*.

fetus The unborn human offspring from the third month of pregnancy to birth.

fiber (1) In plants, a type of sclerenchyma cell; fibers are long, tapered cells with thick walls. Compare with *scleireid*. (2) In animals, an elongated cell such as a muscle or nerve cell. (3) In animals, the microscopic, threadlike protein and carbohydrate complexes scattered through the matrix of connective tissues.

fibrin An insoluble protein formed from the plasma protein fibrinogen during blood clotting.

fibroblasts Connective tissue cells that produce the fibers and the protein and carbohydrate complexes of the matrix of connective tissues.

fibronectins Glycoproteins of the extracellular matrix that bind to integrins (receptor proteins in the plasma membrane).

fibrous root system A root system consisting of several adventitious roots of approximately equal size that arise from the base of the stem. Compare with *taproot system*.

Fick's law of diffusion A physical law governing rates of gas exchange in animal respiratory systems; states that the rate of diffusion of a substance across a membrane is directly proportional to the surface area and to the difference in pressure between the two sides.

fibrinogen A soluble plasma protein that is converted to the insoluble protein fibrin during blood clotting.

filament (1) In flowering plants, the thin stalk of a stamen; the filament bears an anther at its tip. (2) In muscles, a myofilament; when myofilaments slide past one another, muscle contraction occurs.

fimbriae Hairlike structures that project from the cell surface of some prokaryotes; help bacteria to adhere to one another and to attach to the surfaces of cells they infect.

first law of thermodynamics The law of conservation of energy, which states that the total energy of any closed system (any object plus its surroundings, i.e., the universe) remains constant. Compare with the *second law of thermodynamics*.

first messenger A signaling molecule that binds to a receptor on the cell surface, initiating a signal transduction process that leads to the formation of an intracellular *second messenger*.

fissure A groove or furrow, for example the grooves between the convolutions of the cerebral cortex.

fitness See *direct fitness*.

fixed action pattern (FAP) An innate behavior triggered by a sign stimulus.

flagellate A unicellular nonphotosynthetic protist that has one or more long, whiplike flagella.

flagellum (flah-jel'-um) (pl., *flagella*) A long, whiplike structure extending from certain cells and used in locomotion. (1) Eukaryote flagella consist of two central, single microtubules surrounded by nine double microtubules (9 + 2 structure), all covered by a plasma membrane. (2) Bacterial flagella are filaments rotated by special structures located in the plasma membrane and cell wall. (3) Archaea have a rotating appendage, an *archaellum*, for motility.

flame cells Collecting cells that have cilia; part of the osmoregulatory system of flatworms.

flavin adenine dinucleotide See *FAD/FADH₂*.

flowering plants See *angiosperms*.

flowing-water ecosystem A river or stream ecosystem.

fluid mosaic model The currently accepted model of the plasma membrane and other cell membranes, in which protein molecules "float" in a fluid phospholipid bilayer.

fluorescence The emission of light of a longer wavelength (lower energy) than the light originally absorbed.

fluorescent in situ hybridization (FISH) A technique to detect specific DNA segments by hybridization directly to chromosomes; visualized microscopically by using a fluorescent dye.

follicle (fol'-i-kl) (1) A simple, dry, dehiscent fruit that develops from a single carpel and splits open at maturity along one suture to liberate the seeds. (2) A small sac of cells in the mammalian ovary that contains a maturing egg. (3) The pocket in the skin from which a hair grows.

follicle-stimulating hormone (FSH) A gonadotropic hormone secreted by the anterior lobe of the pituitary gland; stimulates follicle development in the ovaries of females and sperm production in the testes of males.

food chain The series of organisms through which energy flows in an ecosystem. Each organism in the series eats or decomposes the preceding organism in the chain. See *food web*.

food web A complex interconnection of all the food chains in an ecosystem.

foraging Feeding behavior; involves locating and selecting food, as well as capturing and gathering it.

foram See *foraminiferan*.

foramen magnum The opening in the vertebrate skull through which the spinal cord passes.

foraminiferan (for'-am-in-'er-an) A marine protist that produces a shell, or test, that encloses an amoeboid body. Also called *foram*. See *rhizarians*.

forebrain In the early embryo, one of the three divisions of the developing vertebrate brain; subdivides to form the telencephalon, which gives rise to the cerebrum, and the diencephalon, which gives rise to the thalamus and hypothalamus. Compare with *midbrain* and *hindbrain*.

forest decline A gradual deterioration (and often death) of many trees in a forest; can be caused by a combination of factors, such as acid precipitation, toxic heavy metals, and surface-level ozone.

fossil Parts or traces of an ancient organism usually preserved in rock.

fossil fuel Combustible deposits in Earth's crust that are composed of the remnants of prehistoric organisms that existed millions of years ago (e.g., oil, natural gas, and coal).

founder cell A cell from which a particular cell lineage is derived.

founder effect Genetic drift that results from a small population colonizing a new area.

fovea (foe'-vee-ah) The area of sharpest vision in the retina; cone cells are concentrated here.

fragile site A weak point at a specific location on a chromosome where part of a chromatid appears attached to the rest of the chromosome by a thin thread of DNA.

fragile X syndrome A human genetic disorder caused by a fragile site that occurs near the tip on the X chromosome; effects range from mild learning disabilities to severe intellectual disability and hyperactivity.

fragmentation A method of asexual reproduction in some bacteria, archaea, animals, or plants; a cell or an organism separates into several pieces and each piece develops into a new organism.

frameshift mutation A mutation that results when one or two nucleotide pairs are inserted into or deleted from the DNA. The change causes the mRNA transcribed from the mutated DNA to have an altered reading frame such that all codons downstream from the mutation are changed.

fraternal twins See *dizygotic twins*.

free energy The maximum amount of energy available to do work under the conditions of a biochemical reaction.

free radicals Toxic, highly reactive compounds with unpaired electrons that bond with other compounds in the cell and interfere with normal function.

frequency-dependent selection Selection in which the relative fitness of different genotypes is related to how frequently they occur in the population.

freshwater wetlands Land that is transitional between freshwater and terrestrial ecosystems and is covered with water for at least part of the year (e.g., marshes and swamps).

frontal lobes Include the region of the cerebral cortex anterior to the central sulcus; contain important association and motor areas.

fruit In flowering plants, a mature, ripened ovary. Fruits contain seeds and usually provide seed protection and dispersal.

fruiting body A multicellular structure that contains the sexual spores of certain fungi; refers to the ascocarp of an ascomycete and the basidiocarp of a basidiomycete.

fucoxanthin (few'-koh-zan'-thin) The brown carotenoid pigment found in brown algae, golden algae, diatoms, and dinoflagellates.

functional genomics The study of the roles of genes in cells.

functional group A group of atoms that confers distinctive properties on an organic molecule (or region of a molecule) to which it is attached (e.g., hydroxyl, carbonyl, carboxyl, amino, phosphate, and sulfhydryl groups).

fundamental niche The potential ecological niche that an organism could occupy if there were no competition from other species. Compare with *realized niche*.

fungus (pl., *fungi*) A heterotrophic eukaryote belonging to the opisthokont clade, with chitinous cell walls and a body usually in the form of a mycelium of branched, threadlike hyphae. Most fungi are decomposers; some are parasitic.

G protein One of a group of proteins that bind GTP and are involved in the transfer of signals across the plasma membrane.

G protein-linked receptors Cell surface receptors that activate a G protein in response to binding by a signaling molecule.

G₁ phase The first gap phase within the interphase stage of the cell cycle; G₁ occurs before DNA synthesis (S phase) begins. Compare with *S phase* and *G₂ phase*.

G₂ phase Second gap phase within the interphase stage of the cell cycle; G₂ occurs after DNA synthesis (S phase) and before mitosis. Compare with *S phase* and *G₁ phase*.

gallbladder A small sac that stores bile.

gametangium (gam"-uh-tan'-gee-um) Special multicellular or unicellular structure of plants, protists, and fungi in which gametes are formed.

gamete (gam'-eet) A sex cell; in plants and animals, an egg or sperm. In sexual reproduction, the union of gametes results in the formation of a zygote. The chromosome number of a gamete is designated *n*.

gametic isolation (gam-ee'-tik) A prezygotic reproductive isolating mechanism in which sexual reproduction between two closely related species cannot occur because of chemical differences in the gametes.

gametogenesis The process of gamete formation. See *spermatogenesis* and *oogenesis*.

gametophyte generation (gam-ee'-toh-fite) The *n*, gamete-producing stage in the life cycle of a plant. Compare with *sporophyte generation*.

gamma-aminobutyric acid (GABA) A neurotransmitter that has an inhibitory effect.

ganglion (gang'-glee-on) (pl., *ganglia*) A mass of neuron cell bodies; in vertebrates, refers to aggregations of cell bodies in the peripheral nervous system. Compare with *nucleus* (definition 3).

ganglion cell A type of neuron in the retina of the eye; receives input from bipolar cells.

gap junction Structure consisting of specialized regions of the plasma membrane of two adjacent cells; contains numerous pores that allow the passage of certain small molecules and ions between them.

gastric glands Glands in the wall of the stomach; contain cells that secrete hydrochloric acid, intrinsic factor, and pepsinogen, the precursor of the enzyme pepsin.

gastrin (gas'-trin) A hormone released by the stomach mucosa; stimulates the gastric glands to secrete pepsinogen.

gastrovascular cavity A central digestive cavity with a single opening that functions as both mouth and anus; characteristic of cnidarians and flatworms.

gastrula (gas'-troo-lah) A three-layered embryo formed by the process of gastrulation.

gastrulation (gas-troo-lay'-shun) Process in embryonic development during which the three germ layers (ectoderm, mesoderm, and endoderm) form.

gel electrophoresis Procedure by which proteins or nucleic acids are separated on the basis of size and charge as they migrate through a gel in an electric field.

gemmae (sing., *gemma*) Tiny balls of tissue (borne in *gemmae cups*) used for asexual reproduction by liverworts.

gene A segment of DNA that serves as a unit of hereditary information; includes a transcribable DNA sequence (plus associated sequences regulating its transcription) that yields a protein or RNA product with a specific function.

gene amplification The developmental process in which certain cells produce multiple copies of a gene by selective replication, thus allowing for increased synthesis of the gene product. Compare with *nuclear equivalence* and *genomic rearrangement*.

gene drive A method that increases the chance (above normal Mendelian expectations) that a gene will be transmitted to the offspring, resulting in an increase in the proportion of individuals that will inherit the gene in successive generations.

gene flow The movement of alleles between local populations due to the migration of individuals; can have significant evolutionary consequences.

gene locus See *locus*.

gene pool All the alleles of all the genes present in a freely interbreeding population.

gene therapy Any of a variety of methods designed to correct a disease or alleviate its symptoms through the introduction of normal, therapeutic genes into the affected person's cells.

genetic bottleneck See *bottleneck*.

genetic code See *codon*.

genetic counseling Medical and genetic information provided to persons who are concerned about the risk of abnormality in their children.

genetic diversity Genetic variety within a species both among individuals within a given population and among geographically separate populations.

genetic drift A random change in allele frequency in a small breeding population.

genetic engineering Manipulation of genes, often through recombinant DNA technology. Also called *molecular modification*.

genetic equilibrium The condition of a population that is not undergoing evolutionary change (i.e., in which allele and genotype frequencies do not change from one generation to the next). See *Hardy-Weinberg principle*.

genetic polymorphism (pol"-ee-mor'-fizm) The presence in a population of two or more alleles for a given gene locus.

genetic recombination See *recombination*, *genetic*.

genetics The science of heredity; includes genetic similarities and genetic variation between parents and offspring or among individuals of a population.

genetic screening A systematic search through a population for individuals with a genotype or karyotype that might cause a serious genetic disease in them or their offspring.

genetic variation Inherited differences among individuals.

genome (jee'-nome) Originally, all the genetic material in a cell or individual organism. The term is used in more than one way depending on context (e.g., an organism's haploid genome is all the DNA contained in one haploid set of its chromosomes, and its mitochondrial genome is all the DNA in a mitochondrion). See *human genome*.

genome-wide association study (GWAS) A comparison of differences in the entire genomes of a population of individuals (e.g., single nucleotide polymorphisms [SNPs], DNA insertions, deletions, or copy number variations).

genomic imprinting See *imprinting* (definition 1).

genomic rearrangement A physical change in the structure of one or more genes that occurs during the development of an organism and leads to an alteration in gene expression; compare with *nuclear equivalence* and *gene amplification*.

genomics The emerging field of biology that studies the entire DNA sequence of an organism's genome to identify all the genes, determine their RNA or protein products, and ascertain how the genes are regulated.

genotype (jeen'-oh-type) The genetic makeup of, or combination of alleles in, an individual. Compare with *phenotype*.

genotype frequency The proportion of a particular genotype in the population. Compare with *allele frequency* and *phenotype frequency*.

genus (jee'-nus) A taxonomic category made up of related species.

geographic variation Genetic differences that may exist among different populations within the same species. See *cline* for an example of one type of geographic variation.

geometric isomer One of two or more chemical compounds having the same arrangement of covalent bonds but differing in the spatial arrangement of their atoms or groups of atoms.

germination Resumption of growth of an embryo or spore; occurs when a seed or spore sprouts.

germ layers In animals, three embryonic tissue layers: endoderm, mesoderm, and ectoderm.

germ line cell In animals, a cell that is part of the line of cells that will ultimately undergo meiosis to form gametes. Compare with *somatic cell*.

germplasm Any plant or animal material that may be used in breeding; includes seeds, plants, and plant tissues of traditional crop varieties and the sperm and eggs of traditional livestock breeds.

ghrelin (grell'-in) A peptide hormone that stimulates appetite; secreted by the stomach.

gibberellin (jib'-ur-el'-lin) A plant hormone involved in many aspects of plant growth and development, such as stem elongation, flowering, and seed germination.

gigantism Abnormally tall growth caused when anterior pituitary secretes excessive amounts of human growth hormone during childhood.

gills (1) Moist, thin structures that extend outward from the body surface onto a respiratory medium (water or air); surfaces for gas exchange, mainly in aquatic animals. (2) The spore-bearing, platelike structures under the caps of mushrooms.

ginkgo (ging'-ko) A member of an ancient gymnosperm group that consists of a single living representative (*Ginkgo biloba*), a hardy, deciduous tree with broad, fan-shaped leaves and naked, fleshy seeds (on female trees).

gland See *endocrine gland* and *exocrine gland*.

glial cells (glee'-ul) In nervous tissue, cells that support and nourish neurons; they also communicate with neurons and have several other functions; also see *astrocyte*, *oligodendrocyte*, *ependymal cells*, and *microglia*.

globulin (glob'-yoo-lin) One of a class of proteins in blood plasma, some of which (gamma globulins) function as antibodies.

glomeromycetes A group of endomycorrhizal fungi that form arbuscular mycorrhizae with the roots of many plants; belong to phylum Glomeromycota.

glomerular filtration The process by which plasma is forced out of the capillaries and into Bowman's capsule as blood flows through the glomerular capillaries at high pressure; it is the first step in the production of urine.

glomerulus (glom-air'-yoo-lus) The cluster of capillaries at the proximal end of a nephron; the glomerulus is surrounded by Bowman's capsule.

glucagon (gloo'-kah-gahn) A hormone secreted by the pancreas that stimulates glycogen breakdown, thereby increasing the concentration of glucose in the blood. Compare with *insulin*.

glucocorticoids Steroid hormones, particularly *cortisol*, produced by the adrenal cortex that are involved in carbohydrate, protein, and fat metabolism. Glucocorticoids have anti-inflammatory properties.

glucose A hexose aldehyde sugar that is central to many metabolic processes.

glutamate An amino acid that functions as the major excitatory neurotransmitter in the vertebrate brain.

glyceraldehyde-3-phosphate (G3P) Phosphorylated 3-carbon compound that is an important intermediate in glycolysis and in the Calvin cycle.

glycerol A 3-carbon alcohol with a hydroxyl group on each carbon; a component of triacylglycerols and phospholipids, as well as monoacylglycerols and diacylglycerols.

glycine An amino acid that is the main inhibitory neurotransmitter in the spinal cord.

glycocalyx (gly'-koh-kay'-lix) A coating on the outside of an animal cell, formed by the polysaccharide portions of glycoproteins and glycolipids associated with the plasma membrane.

glycogen (gly'-koh-jen) The principal storage polysaccharide in animal cells; formed from glucose and stored primarily in the liver and, to a lesser extent, in muscle cells.

glycolipid A lipid with covalently attached carbohydrates.

glycolysis (gly-kol'-ih-sis) The first stage of cellular respiration as well as fermentation; literally the "splitting of sugar." The metabolic conversion of glucose into pyruvate, accompanied by the production of ATP.

glycoprotein (gly'-koh-pro-teen) A protein with covalently attached carbohydrates.

glycosidic linkage Covalent linkage joining two sugars; includes an oxygen atom bonded to a carbon of each sugar.

glyoxysomes (gly-ox'-ih-sohmz) Membrane-enclosed structures in cells of certain plant seeds; contain a large array of enzymes that convert stored fat to sugar.

gnathostomes (nath'-o-stomes) Vertebrates with jaws.

gnetophyte (nee'-toe-fite) One of a small phylum of unusual gymnosperms that have some features similar to those of flowering plants.

goblet cells Unicellular glands that secrete mucus.

goiter (goy'-ter) An enlargement of the thyroid gland.

golden alga A member of a group of algae, most of which are biflagellate, are unicellular, and contain pigments, including chlorophylls *a* and *c*, and carotenoids, including fucoxanthin.

Golgi complex (goal'-jee) Organelle composed of stacks of flattened, membranous sacs. Mainly responsible for modifying, packaging, and sorting proteins that will be secreted or targeted to other organelles of the internal membrane system or to the plasma membrane; also called *Golgi body* or *Golgi apparatus*.

Golgi tendon organ (goal'-jee) A proprioceptor that responds to tension in contracting muscles and in the tendons that attach muscle to bone.

gonad (goh'-nad) A gamete-producing gland; an ovary or a testis.

gonadotropic hormones (go-nad-oh-troh'-pic) Hormones produced by the anterior pituitary gland that stimulate the testes and ovaries;

include follicle-stimulating hormone (FSH) and luteinizing hormone (LH).

gonadotropin-releasing hormone (GnRH) A hormone secreted by the hypothalamus that stimulates the anterior pituitary to secrete the gonadotropic hormones: follicle-stimulating hormone (FSH) and luteinizing hormone (LH).

graded potential A local change in electrical potential that varies in magnitude depending on the strength of the applied stimulus.

gradualism See *phyletic gradualism*.

graft rejection An immune response directed against a transplanted tissue or organ.

grain A simple, dry, one-seeded fruit in which the fruit wall is fused to the seed coat (e.g., corn and wheat kernels). Also called *caryopsis*.

gram-negative bacteria Bacteria with cell walls consisting of a thin peptidoglycan layer and a thick outer membrane. Compare with *gram-positive bacteria*.

gram-positive bacteria Bacteria with cell walls that are very thick and consist mainly of peptidoglycan. Compare with *gram-negative bacteria*.

granulosa cells In mammals, cells that surround the developing oocyte and are part of the follicle; produce estrogens and inhibin.

granum (pl., *grana*) A stack of thylakoids within a chloroplast.

Graves' disease Common form of hyperthyroidism, an autoimmune disease, characterized by extreme weight loss and emotional irritability.

gravitropism (grav'-ih-troh'-pizm) Growth of a plant in response to gravity.

gray crescent The grayish area of cytoplasm that marks the region where gastrulation begins in an amphibian embryo.

gray matter Nervous tissue in the brain and spinal cord that contains cell bodies, dendrites, and unmyelinated axons. Compare with *white matter*.

greater omentum A sheet of fatty tissue that hangs down over the intestine, providing protection.

green alga A member of a diverse group of archaeplastid algae that contain the same pigments as plants (chlorophylls *a* and *b* and carotenoids).

greenhouse effect The natural global warming of Earth's atmosphere caused by the presence of carbon dioxide and other gases that trap the sun's radiation. The additional warming produced when increased levels of greenhouse gases absorb infrared radiation is known as the *enhanced greenhouse effect*.

greenhouse gases Trace gases in the atmosphere that allow the sun's energy to penetrate to Earth's surface but do not allow as much of it to escape as heat.

gross primary productivity (GPP) The rate at which energy accumulates (is assimilated) in an ecosystem during photosynthesis. Compare with *net primary productivity (NPP)*.

ground state The lowest energy state of an atom.

ground tissue system All tissues in the plant body other than the dermal tissue system and vascular tissue system; consists of parenchyma, collenchyma, and sclerenchyma.

groundwater Water stored underground in soil and crevasses, or an aquifer.

growth factors A group of more than 50 extracellular peptides that signal certain cells to grow and divide.

growth hormone (GH) A hormone secreted by the anterior lobe of the pituitary gland; stimulates growth of body tissues; also called *somatotropin*.

growth hormone-inhibiting hormone (GHIH) Hormone secreted by the hypothalamus that inhibits growth hormone (GH) secretion.

growth hormone-releasing hormone (GHRH) Hormone secreted by the hypothalamus that permits growth hormone (GH) secretion.

growth rate (r) The rate of change of a population's size on a per capita basis.

guanine (gwan'-een) A nitrogenous purine base that is a component of nucleic acids and GTP.

guanosine diphosphate (GDP) See *guanosine triphosphate*.

guanosine triphosphate (GTP) An energy transfer molecule similar to ATP that releases free energy with the hydrolysis of its terminal phosphate group, yielding guanosine diphosphate (GDP).

guard cell One of a pair of epidermal cells that adjust their shape to form a stomatal pore for gas exchange.

guide RNA An RNA molecule encoded by a CRISPR locus; consists of a repeated nucleotide sequence that binds to a Cas endonuclease, fused to a unique nucleotide sequence that binds to a DNA region that will be cut by the endonuclease.

guttation (gut-tay'-shun) The appearance of water droplets on leaves, forced out through leaf pores by root pressure.

gymnosperm (jim'-noh-sperm) Any of a group of seed plants in which the seeds are not enclosed in an ovary; gymnosperms frequently bear their seeds in cones. Includes four phyla: conifers, cycads, ginkgoes, and gnetophytes.

habitat The natural environment or place where an organism, population, or species lives.

habitat corridors Strips of land connecting isolated habitat patches that allow wildlife to pass through freely.

habitat fragmentation The division of habitats that formerly occupied large, unbroken areas into smaller pieces by roads, fields, cities, and other human land-transforming activities.

habitat isolation A prezygotic reproductive isolating mechanism in which reproduction between similar species is prevented because they live and breed in different habitats.

habituation (hab-it'-yoo-ay'-shun) A type of learning in which an animal becomes accustomed to a repeated, irrelevant stimulus and no longer responds to it.

hadal zone Part of the benthic environment of the ocean deeper than 6000 m.

hagfishes Jawless marine fishes with a notochord for axial support; lack vertebrae and paired appendages.

hair cells Vertebrate mechanoreceptors that detect movement.

half-life The period of time required for a radioisotope to change into a different material.

haploid (hap'-loyd) The condition of having one set of chromosomes per nucleus. Compare with *diploid* and *polyploid*.

“hard-wiring” Refers to how neurons signal one another, how they connect, and how they carry out basic functions such as regulating heart rate, blood pressure, and sleep-wake cycles.

Hardy–Weinberg principle The mathematical prediction that allele frequencies do not change from generation to generation in a large population in the absence of microevolutionary processes (mutation, genetic drift, gene flow, natural selection).

haustorium (hah-stor'-ee-um) (pl., *haustoria*) In parasitic fungi, a specialized hypha that penetrates a host cell and obtains nourishment from the cytoplasm.

Haversian canals (ha-vur'-zee-un) Channels extending through the matrix of bone; contain blood vessels and nerves.

heat The total amount of kinetic energy in a sample of a substance.

heat energy The thermal energy that flows from an object with a higher temperature to an object with a lower temperature.

heat of vaporization The amount of heat energy that must be supplied to change one gram of a substance from the liquid phase to the vapor phase.

helicases Enzymes that unwind the two strands of a DNA double helix.

helper T cell See *T helper cell*.

hemichordates A phylum of sedentary, wormlike deuterostomes.

hemizygous (hem'-ih-zy'-gus) Possessing only one allele for a particular locus; a human male is hemizygous for all X-linked genes. Compare with *homozygous* and *heterozygous*.

hemocoel Blood cavity characteristic of animals with an open circulatory system.

hemocyanin A hemolymph pigment that transports oxygen in some mollusks and arthropods.

hemoglobin (hee'-moh-gloh'-bin) The red, iron-containing protein pigment in blood that transports oxygen and carbon dioxide and aids in regulation of pH.

hemolymph (hee'-moh-limf) The fluid that bathes the tissues in animals with an open circulatory system (e.g., arthropods and most mollusks).

hemophilia (hee'-moh-feel'-ee-ah) A hereditary disease in which blood does not clot properly; the forms known as *hemophilia A* (deficient for clotting factor VIII) and *hemophilia B* (deficient for clotting factor IX) exhibit an X-linked, recessive inheritance pattern.

Hensen's node See *primitive streak*.

hepatic (heh-pat'-ik) Pertaining to the liver.

hepatic portal system The portion of the circulatory system that carries blood from the intestine through the liver.

herbivore (erb'-uh-vore) An animal that feeds on plants or algae. Also called *primary consumer*.

heredity The transmission of genetic information from parent to offspring.

hermaphrodite (her-maf'-roh-dite) An organism that has both male and female sex organs; hermaphroditism is the form of sexual

reproduction in which a single individual produces both eggs and sperm.

hermaphroditism See *hermaphrodite*.

heterochromatin (het'-ur-oh-kroh'-mah-tin) Highly coiled and compacted chromatin in an inactive state. Compare with *euchromatin*.

heterocyst (het'-ur-oh-sist') An oxygen-excluding cell of cyanobacteria that is the site of nitrogen fixation.

heterogametic A term describing an individual that produces two classes of gametes with respect to their sex chromosome constitutions. Human males (XY) are heterogametic, producing X and Y sperm. Compare with *homogametic*.

heterosporous (het'-ur-os'-pur-ee) Production of two types of *n* spores, microspores (male) and megaspores (female). Compare with *homosporous*.

heterothallic (het'-ur-oh-thal'-ik) Pertaining to certain algae and fungi that have two mating types; only by combining a plus strain and a minus strain can sexual reproduction occur. Compare with *homothallic*.

heterotroph (het'-ur-oh-trof) An organism that cannot synthesize its own food from inorganic raw materials and therefore must obtain body-building materials from other organisms. Also called *consumer*. Compare with *autotroph*. See *chemoheterotroph* and *photoheterotroph*.

heterozygote advantage A phenomenon in which the heterozygous condition confers some special advantage on an individual that either homozygous condition does not (i.e., *Aa* has a higher degree of fitness than does *AA* or *aa*).

heterozygous (het-ur'-oh-zye'-gus) Having a pair of unlike alleles for a particular locus. Compare with *homozygous*.

hexose A monosaccharide containing six carbon atoms.

hibernation Long-term torpor in response to winter cold and scarcity of food. Compare with *estivation*.

high-density lipoprotein (HDL) See *lipoprotein*.

hindbrain In the early embryo, one of the three divisions of the developing vertebrate brain; subdivides to form the metencephalon, which gives rise to the cerebellum and pons, and the myelencephalon, which gives rise to the medulla. Compare with *forebrain* and *midbrain*.

hippocampus Part of the limbic system; important in forming and retrieving declarative memories.

histamine (his'-tah-mein) Substance released from mast cells that causes inflammation.

histones (his'-tohnz) Small, positively charged (basic) proteins in the cell nucleus that bind to the negatively charged DNA. See *nucleosomes*.

holdfast The basal structure for attachment to solid surfaces found in multicellular algae.

holoblastic cleavage A cleavage pattern in which the entire embryo cleaves; characteristic of eggs with little or moderate yolk (isolecithal or moderately telolecithal) (e.g., the eggs of echinoderms, amphioxus, and mammals). Compare with *meroblastic cleavage*.

homeobox A short (180-nucleotide) DNA sequence that characterizes many homeotic genes as well as some other genes that play a role in development.

homeodomain A functional region of certain transcription factors; consists of approximately 60 amino acids specified by a homeobox DNA sequence and includes a recognition alpha helix, which binds to specific DNA sequences and affects their transcription.

homeostasis (home"-ee-oh-stay'-sis) The balanced internal environment of the body; the automatic tendency of an organism to maintain such a steady state.

homeostatic mechanisms (home"-ee-oh-stat'-ik) The regulatory mechanisms that maintain homeostasis.

homeotic gene (home"-ee-ah'-tik) A gene that controls the formation of specific structures during development. Such genes were originally identified through insect mutants in which one body part is substituted for another.

home range A geographic area that an individual animal seldom or never leaves. Compare with *range*.

hominid See *hominin*.

hominin (hah'-min-in) Any of a group of extinct and living humans. Also called *hominid*.

hominoid (hah'-min-oid) The apes and hominins (hominids).

Homo antecessor Early humans living in about 1.2 mya to 800,000 years ago; some scientists believe that they should be classified with *Homo heidelbergensis*.

Homo erectus Species that originated in Africa about 1.7 mya and then spread to Europe and Asia; may have persisted until 200,000 years ago or later; may be an evolutionary dead end.

Homo ergaster African species that lived from about 2.0 to 1.4 mya; may be a direct ancestor of later humans.

Homo habilis Oldest known species in genus *Homo*; lived in Africa from approximately 2.5 to 1.6 mya.

Homo heidelbergensis Early humans living from about 600,000 to 300,000 years ago; some scientists believe that fossils classified as *Homo antecessor* should be included in *Homo heidelbergensis*.

Homo neanderthalensis Human species living in Europe and western Asia from about 250,000 to 28,000 years ago; may have interbred with modern humans (*Homo sapiens*).

Homo sapiens Modern human species.

homogametic Term describing an individual that produces gametes with identical sex chromosome constitutions. Human females (XX) are homogametic, producing all X eggs. Compare with *heterogametic*.

homologous chromosomes (hom-ol'-ah-gus) Chromosomes that are similar in morphology and genetic constitution. In humans there are 23 pairs of homologous chromosomes; one member of each pair is inherited from the mother, and the other from the father.

homologous DNA repair A cellular process in which a mutated or deleted DNA sequence is replaced by a copy of a homologous sequence.

homologous features See *homology*.

homologous traits See *homology*.

homology Similarity in different species that results from their derivation from a common ancestor. The features that exhibit such similarity are called *homologous features* or *homologous traits*. Compare with *homoplasy*.

homoplastic features See *homoplasy*.

homoplastic traits See *homoplasy*.

homoplasy Similarity in the characters in different species that is due to convergent evolution, not common descent. Characters that exhibit such similarity are called *homoplastic features* or *homoplastic traits*. Compare with *homology*.

homospory (hoh"-mos'-pur-ee) Production of one type of *n* spore that gives rise to a bisexual gametophyte. Compare with *heterospory*.

homothallic (hoh"-moh-thal'-ik) Pertaining to certain algae and fungi that are self-fertile. Compare with *heterothallic*.

homozygous (hoh"-moh-zy'-gous) Having a pair of identical alleles for a particular locus. Compare with *heterozygous*.

horizontal cell A lateral interneuron in the retina of the eye; receives signals from the photoreceptor cells and sends signals to bipolar cells and amacrine cells.

horizontal gene transfer The (nonsexual) lateral transfer of genetic material from one genome to another within a species or from one species to another species at any taxonomic level, including from a species in one domain to a species in another domain. Compare with *vertical gene transfer*.

hormone A chemical messenger, often produced in one region of the body of a multicellular organism and transported to another region where it signals cells to alter some aspect of growth, development, or metabolism.

hornwort A phylum of spore-producing, nonvascular, thallose plants with a life cycle similar to that of mosses.

horsetails Fern relatives with hollow, jointed stems, to which tiny leaves (reduced megaphylls) are attached in whorls.

host Organism that is adversely affected by a parasite member in a symbiotic relationship.

host mothering The introduction of an embryo from one species into the uterus of another species, where it implants and develops; the host mother subsequently gives birth and may raise the offspring as her own.

host range The specific types of host species a specific infectious agent can infect.

Hox genes Clusters of homeobox-containing genes that specify the anterior-posterior axis of various animals during development.

human chorionic gonadotropin (hCG) A hormone secreted by cells surrounding the early embryo; signals the mother's corpus luteum to continue to function.

human genetics The science of inherited variation in humans.

human genome The totality of genetic information in human cells; includes the DNA content of both the nucleus and mitochondria. See *genome*.

Human Genome Project Initiative completed in 2003 to determine the sequence of bases for a human haploid reference genome of more than 3 billion nucleotide base pairs.

human immunodeficiency virus (HIV) The retrovirus that causes AIDS (acquired immunodeficiency syndrome).

human leukocyte antigen complex (HLA) The MHC in humans. See *major histocompatibility complex*.

humus (hew'-mus) Organic matter in various stages of decomposition in the soil; gives soil a dark brown or black color.

Huntington's disease A genetic disease that has an autosomal dominant inheritance pattern and causes mental and physical deterioration.

hybrid The offspring of two genetically dissimilar parents.

hybrid breakdown A postzygotic reproductive isolating mechanism in which, although an interspecific hybrid is fertile and produces a second (F₂) generation, the F₂ has defects that prevent it from successfully reproducing.

hybrid inviability A postzygotic reproductive isolating mechanism in which the embryonic development of an interspecific hybrid is aborted.

hybridization (1) Interbreeding between members of two different taxa. (2) Interbreeding between genetically dissimilar parents. (3) In molecular biology, complementary base pairing between nucleic acid (DNA or RNA) strands from different sources.

hybrid sterility A postzygotic reproductive isolating mechanism in which an interspecific hybrid cannot reproduce successfully.

hybrid vigor The genetic superiority of an F₁ hybrid over either parent, caused by the presence of heterozygosity for a number of different loci.

hybrid zone An area of overlap between two closely related populations, subspecies, or species in which interbreeding occurs.

hydration Process of association of a substance with the partial positive and/or negative charges of water molecules.

hydrocarbon An organic compound composed solely of hydrogen and carbon atoms.

hydrogen bond A weak attractive force existing between a hydrogen atom with a partial positive charge and an electronegative atom (usually oxygen or nitrogen) with a partial negative charge. Compare with *covalent bond* and *ionic bond*.

hydrologic cycle The water cycle, which includes evaporation, precipitation, and flow to the ocean; supplies terrestrial organisms with a continual supply of fresh water.

hydrolysis reaction Reaction in which a covalent bond between two subunits is broken through the addition of the equivalent of a water molecule; a hydrogen atom is added to one subunit and a hydroxyl group to the other. Compare with *condensation reaction*.

hydrophilic Interacting readily with water; having a greater affinity for water molecules than they have for each other. Compare with *hydrophobic*.

hydrophobic Not readily interacting with water; having less affinity for water molecules than they have for each other. Compare with *hydrophilic*.

hydrophobic interactions The tendency of hydrophobic substances to cluster together due to strong cohesive interactions among surrounding water molecules.

hydroponics (hy"-dra-paun'-iks) Growing plants in an aerated solution of dissolved inorganic minerals (i.e., without soil).

hydrostatic skeleton A type of skeleton found in some invertebrates in which contracting muscles push against a tube of fluid.

hydrothermal vents Fissures in the deep ocean floor that release hot water and inorganic compounds.

hydroxide ion An anion (negatively charged particle) consisting of oxygen and hydrogen; usually written OH⁻.

hydroxyl group (hy-drok'-sil) Polar functional group; abbreviated —OH.

hyperpolarize To change the membrane potential so that the inside of the cell becomes more negative than its resting potential.

hyperpolarized The condition of the neuron membrane when the inside of the cell becomes more negative than its resting potential.

hypersecretion Abnormally increased output of a secreted material. Compare with *hyposecretion*.

hypertension Sustained, above normal, mean arterial blood pressure.

hypertonic A term referring to a solution having an osmotic pressure (or solute concentration) greater than that of the solution with which it is compared. Compare with *hypotonic* and *isotonic*.

hypha (hy'-fah) (pl., *hyphae*) One of the threadlike filaments composing the mycelium of a water mold or fungus.

hypocotyl (hy'-poh-kah'-tl) The part of the axis of a plant embryo or seedling below the point of attachment of the cotyledons.

hyposecretion Abnormally reduced output of a secreted material. Compare with *hypersecretion*.

hypothalamus (hy-poh-thal'-uh-mus) Part of the vertebrate brain; in mammals it regulates the pituitary gland, the autonomic system, emotional responses, body temperature, water balance, and appetite; located below the thalamus.

hypothesis A testable statement about the nature of an observation or relationship. Compare with *scientific theory*.

hypothetico-deductive approach Emphasizes the use of deductive reasoning to test hypotheses. Compare with *hypothetico-inductive approach*. See *deductive reasoning*.

hypothetico-inductive approach Emphasizes the use of inductive reasoning to discover new general principles. Compare with *hypothetico-deductive approach*. See *inductive reasoning*.

hypotonic A term referring to a solution having an osmotic pressure (or solute concentration) less than that of the solution with which it is compared. Compare with *hypertonic* and *isotonic*.

hypotrichs A group of dorsoventrally flattened ciliates that exhibit an unusual creeping–darting locomotion.

identical twins See *monozygotic twins*.

illuviation The deposition of material leached from the upper layers of soil into the lower layers.

imaginal discs Paired structures in an insect larva that develop into specific adult structures during complete metamorphosis.

imago (ih-may'-go) The adult form of an insect.

imbibition (im'-bi-bish'-en) The absorption of water by a seed prior to germination.

immigration The movement of individuals into a population. Compare with *emigration*.

immune response Process of recognizing foreign macromolecules and mounting a response aimed at eliminating them. See *innate immune responses*

and *adaptive immune responses*; *primary immune responses* and *secondary immune responses*.

immune system The system of molecules and cells that protect the body against pathogens and other foreign agents. In vertebrates, includes lymphatic vessels and other lymph structures.

immunity The ability to recognize and destroy foreign or dangerous macromolecules.

immunodeficiency disease A condition that increases susceptibility to infection; the condition can be inherited or acquired. HIV is the major cause of acquired immunodeficiency in adults.

immunofluorescence Method used to localize molecules in cells or quantify specific molecules in biochemical assays by observing or measuring light emitted from a fluorescent dye joined to an antibody that binds to the specific molecule under study.

immunoglobulin (im-yoon'-oh-glob'-yoo-lin) See *antibody*.

immunological memory The ability of the immune system to remember antigens after contact with them, allowing more rapid response if it encounters the same antigens again. Memory B cells and memory T cells are responsible for immunological memory.

imperfect flower A flower that lacks either stamens or carpels. Compare with *perfect flower*.

imperfect fungi See *deuteromycetes*.

implantation The embedding of a developing embryo in the inner lining (endometrium) of the uterus.

implicit memory The unconscious memory for perceptual and motor skills (e.g., riding a bicycle).

imprinting (1) The expression of a gene based on its parental origin; also called *genomic imprinting* or *parental imprinting*. (2) A type of learning by which a young bird or mammal forms a strong social attachment to an individual (usually a parent) or object within a few hours after hatching or birth.

inborn error of metabolism A metabolic disorder caused by the mutation of a gene that codes for an enzyme needed for a biochemical pathway.

inbreeding depression The phenomenon in which inbred offspring of genetically similar individuals have lower fitness (e.g., decline in fertility and high juvenile mortality) than do noninbred individuals.

inbreeding The mating of genetically similar individuals. Homozygosity increases with each successive generation of inbreeding. Compare with *outbreeding*.

incisors Chisel-shaped teeth of a mammal; adapted for biting and cutting food. Compare with *canines*, *premolars*, and *molars*.

inclusive fitness The total of an individual's direct and indirect fitness; includes the genes contributed directly to offspring and those contributed indirectly by kin selection. Compare with *direct fitness*. See *kin selection*.

incomplete dominance A condition in which neither member of a pair of contrasting alleles is completely expressed when the other is present.

incomplete flower A flower that lacks one or more of the four parts: sepals, petals, stamens, and/or carpels. Compare with *complete flower*.

incomplete metamorphosis In insects, a life cycle during which the larva resembles the adult

in many ways, but lacks functional wings and reproductive structures. Compare with *complete metamorphosis*.

independent assortment, principle of The genetic principle, first noted by Gregor Mendel, that states that the alleles of unlinked loci are randomly distributed to gametes.

indeterminate cleavage Type of cleavage characteristic of deuterostomes; during early cleavage each cell has the potential of developing into a complete embryo. Compare with *determinate cleavage*.

indeterminate growth Unrestricted growth, as for example, in stems and roots. Compare with *determinate growth*.

index fossils Fossils restricted to a narrow period of geologic time and found in the same sedimentary layers in different geographic areas.

individualistic model Independent view of community, described by Gleason, in which biological interactions are less important in the production of communities than are environmental gradients (such as climate and soil) or even chance. Compare with *organismic model*.

indoleacetic acid (IAA) See *auxin*.

induced fit Conformational change in the active site of an enzyme that occurs when it binds to its substrate.

induced pluripotent stem cell (iPSC) A pluripotent stem cell derived by “reprogramming” or modifying the gene expression patterns of an adult somatic cell.

inducer A molecule that binds to a repressor protein, converting it to its inactive form, which is unable to prevent transcription.

inducible operon An operon that is normally inactive because a repressor molecule is attached to its operator; transcription is activated when an inducer binds to the repressor, making it incapable of binding to the operator. Compare with *repressible operon*.

induction The process by which the differentiation of a cell or group of cells is influenced by interactions with neighboring cells.

inductive reasoning The reasoning that uses specific examples to draw a general conclusion or discover a general principle. Compare with *deductive reasoning*. See *hypothetico-inductive approach*.

infant mortality rate The number of infant deaths per 1000 live births. (A child is an infant during his or her first two years of life.)

inferior vena cava In humans, a very large vein that delivers blood from the lower part of the body to the right atrium. Compare with *superior vena cava*.

inflammation The response of body tissues to injury or infection; the body recruits white blood cells and plasma proteins from the blood to the location of an infection resulting in increased dilation of blood vessels and increased phagocytosis.

inflammatory response See *inflammation*.

inflorescence A cluster of flowers on a common floral stalk.

ingestion The process of taking food (or other material) into the body.

ingroup See *outgroup*.

inhibin A hormone that inhibits FSH secretion; produced by Sertoli cells in the testes and by granulosa cells in the ovaries.

inhibiting hormone A hormone secreted by the hypothalamus that inhibits secretion of a specific hormone by the anterior lobe of the pituitary gland.

inhibitory postsynaptic potential (IPSP) A change in membrane potential that takes a neuron farther from the firing level. Compare with *excitatory postsynaptic potential (EPSP)*.

initiation (of protein synthesis) The first steps of protein synthesis, in which the large and small ribosomal subunits and other components of the translation machinery bind to the 5' end of mRNA. See *elongation* and *termination*.

initiation codon See *start codon*.

innate behavior Behavior that is inherited and typical of the species; also called *instinct*.

innate immune responses Mechanisms such as physical barriers (e.g., the skin) and phagocytosis that provide immediate and general protection against pathogens. Also called *nonspecific immune responses* or *nonspecific immunity*. Compare with *adaptive immune responses*.

innate immunity See *innate immune responses*.

inner cell mass The cluster of cells in the early mammalian embryo that gives rise to the embryo proper.

inorganic compound A simple substance that does not contain a carbon backbone. Compare with *organic compound*.

inositol trisphosphate (IP₃) A second messenger that increases intracellular calcium concentration and activates enzymes.

insight learning A complex learning process in which an animal adapts past experience to solve a new problem that may involve different stimuli.

in situ conservation Conservation efforts that concentrate on preserving biological diversity in the wild. Compare with *ex situ conservation*.

instinct See *innate behavior*.

insulin (in'-suh-lin) A hormone secreted by the pancreas that lowers blood glucose concentration. Compare with *glucagon*.

insulin resistance See *diabetes mellitus*.

insulin shock A condition in which the blood glucose concentration is so low that the individual may appear intoxicated or may become unconscious and even die; caused by the injection of too much insulin or by certain metabolic malfunctions.

insulin-like growth factors (IGFs) Proteins that mediate responses to growth hormone.

insulin-like growth factor 2 (IGF2) See *insulin-like growth factors*.

integral membrane protein A protein that is tightly associated with the lipid bilayer of a biological membrane; a transmembrane integral protein spans the bilayer. Compare with *peripheral membrane protein*.

integration The process of summing (adding and subtracting) incoming neural signals.

integrins Receptor proteins that bind to specific proteins in the extracellular matrix and to membrane proteins on adjacent cells; transmit signals into the cell from the extracellular matrix.

integumentary system (in-teg'-yoo-men'-tar-ee) The body's covering, including the skin and its nails, glands, hair, and other associated structures.

integuments The outer cell layers that surround the megasporangium of an ovule; develop into the seed coat.

intercellular substance In connective tissues, the combination of matrix and fibers in which the cells are embedded.

interference competition Intraspecific competition in which certain dominant individuals obtain an adequate supply of the limited resource at the expense of other individuals in the population. Also called *contest competition*. Compare with *exploitation competition*.

interferons (in"-tur-feer'-onz) Cytokines produced by animal cells when challenged by a virus; prevent viral reproduction and enable cells to resist a variety of viruses.

integrator In homeostasis, a control center.

intercalated discs (in-ter'-kuh-lay"-ted) The junctions between cells in cardiac muscle; contain gap junctions.

interkinesis The stage between meiosis I and meiosis II. Interkinesis is usually brief; the chromosomes may decondense, reverting at least partially to an interphase-like state, but DNA synthesis and chromosome duplication do not occur.

interleukins A diverse group of cytokines produced mainly by macrophages and lymphocytes.

intermediate disturbance hypothesis In community ecology, the idea that species richness is greatest at moderate levels of disturbance, which create a mosaic of habitat patches at different stages of succession.

intermediate filaments Cytoplasmic fibers that are part of the cytoskeletal network and are intermediate in diameter between microtubules and microfilaments.

intermediate-day plant A plant that flowers when it is exposed to days and nights of intermediate length but does not flower when the day length is too long or too short. Compare with *long-day*, *short-day*, and *day-neutral plants*.

internal fertilization The process in which the male delivers sperm into the body of the female (or close to the entrance of the reproductive tract). Compare with *external fertilization*.

internal membrane system See *endomembrane system*.

interneuron (in"-tur-noor'-on) A nerve cell that carries impulses from one nerve cell to another and is not directly associated with either an effector or a sensory receptor. Most interneurons are *association neurons*.

internode The region on a stem between two successive nodes. Compare with *node*.

intersexual selection The process by which females select their mates on the basis of some physical trait that indicates genetic quality or good health; sometimes selection depends on some resource offered by the males. Compare with *intrasexual selection*.

interoceptor (in'-tur-oh-sep"-tor) A sense organ within a body organ that transmits information regarding chemical composition, pH, osmotic pressure, or temperature. Compare with *exteroceptor*.

interphase The stage of the cell cycle between successive mitotic divisions; its subdivisions are the

G₁ (first gap), S (DNA synthesis), and G₂ (second gap) phases.

interspecific competition The interaction between members of different species that vie for the same resource in an ecosystem (e.g., food or living space). Compare with *intraspecific competition*.

interstitial cells (of testis) The cells between the seminiferous tubules that secrete testosterone.

interstitial fluid The fluid that bathes the tissues of the body; also called *tissue fluid*.

intertidal zone The marine shoreline area between the high-tide mark and the low-tide mark.

intrasexual selection The process by which individuals of the same sex actively compete for mates. Typically numerous males compete for a limited number of receptive females. Compare with *intersexual selection*.

intraspecific competition The interaction between members of the same species that vie for the same resource in an ecosystem (e.g., food or living space). Compare with *interspecific competition*.

intrinsic rate of increase (r_{max}) The theoretical maximum rate of increase in population size occurring under optimal environmental conditions. Also called *biotic potential*.

intron A non-protein-coding region of a eukaryotic gene and also of the pre-mRNA transcribed from such a region. Introns do not appear in mRNA. Compare with *exon*.

invasive species A foreign species that, when introduced into an area where it is not native, upsets the balance among the organisms living there and causes economic or environmental harm.

inversion A chromosome abnormality in which the breakage and rejoining of chromosome parts results in a chromosome segment that is oriented in the opposite (reverse) direction.

invertebrate An animal without a backbone (vertebral column); invertebrates account for about 95% of animal species.

in vitro Occurring outside a living organism (literally "in glass"). Compare with *in vivo*.

in vitro evolution Test tube experiments that demonstrate that RNA molecules in the RNA world could have catalyzed the many different chemical reactions needed for life. Also called *directed evolution*.

in vitro fertilization The fertilization of eggs in the laboratory prior to implantation in the uterus for development.

in vivo Occurring in a living organism. Compare with *in vitro*.

ion An atom or group of atoms bearing one or more units of electric charge, either positive (cation) or negative (anion).

ion channel-linked receptors Cell surface receptors that open or close specific ion channels in response to binding by a signaling molecule (ligand). Also called *ligand-gated channels*.

ion channels Channels for the passage of ions through a membrane; formed by specific membrane proteins.

ionic bond The chemical attraction between a cation and an anion. Compare with *covalent bond* and *hydrogen bond*.

ionic compound A substance consisting of cations and anions, which are attracted by their opposite

charges; ionic compounds do not consist of molecules. Compare with *covalent compound*.

ionization The dissociation of a substance to yield ions (e.g., the ionization of water yields H^+ and OH^-).

iris The pigmented portion of the vertebrate eye.

iron-sulfur world hypothesis The hypothesis that simple organic molecules that are the precursors of life originated at hydrothermal vents in the deep-ocean floor. Compare with the *prebiotic soup hypothesis*.

irreversible inhibitor A substance that permanently inactivates an enzyme. Compare with *reversible inhibitor*.

islets of Langerhans (eye'-lets of lahng'-er-hanz) The endocrine portion of the pancreas that secretes glucagon and insulin, hormones that regulate the concentration of glucose in the blood.

isogamy (eye-sog'-uh-me) Sexual reproduction involving motile gametes of similar form and size. Compare with *anisogamy* and *oogamy*.

isolecithal egg An egg containing a relatively small amount of uniformly distributed yolk. Compare with *telolecithal egg*.

isomer (eye'-soh-mer) One of two or more chemical compounds having the same chemical formula but different structural formulas (e.g., structural and geometrical isomers and enantiomers).

isoprene units Five-carbon hydrocarbon monomers that make up certain lipids such as carotenoids and steroids.

isotonic (eye"-soh-ton'-ik) A term applied to solutions that have identical concentrations of solute molecules and hence the same osmotic pressure. Compare with *hypertonic* and *hypotonic*.

isotope (eye'-suh-tope) An alternative form of an element with a different number of neutrons but the same number of protons and electrons. See *radioisotopes*.

iteroparous Having repeated reproductive cycles throughout a lifetime. Compare with *semelparous*.

jasmonic acid One of a group of lipid-derived plant hormones that affect several processes, such as pollen development, root growth, fruit ripening, and senescence; also involved in defense against insect pests and disease-causing organisms.

jelly coat One of the acellular coverings of the eggs of certain animals, such as echinoderms.

joint The junction between two or more bones of the skeleton.

joint receptors Proprioceptors that detect movement in ligaments.

joule A unit of energy, equivalent to 0.239 calorie.

Jurassic period See *Mesozoic era*.

juvenile hormone (JH) An arthropod hormone that preserves juvenile structure during a molt. Without it, metamorphosis toward the adult form takes place.

juxtaglomerular apparatus (juks"-tah-glo-mer'-yoo-lar) A structure in the kidney that secretes renin in response to a decrease in blood pressure.

K selection A reproductive strategy recognized by some ecologists in which a species typically has a large body size, slow development, and long lifespan and does not devote a large proportion of its metabolic energy to the production of offspring. Compare with *r selection*.

K strategist See *K selection*.

karyogamy (kar-e-og'-uh-me) The fusion of two haploid nuclei; follows fusion (plasmogamy) of cells from two sexually compatible mating types.

karyotype (kare'-ee-oh-type) The chromosomal composition of an individual.

kelp Large brown alga that grows in shallow ocean areas and forms underwater forests.

keratin (kare'-ah-tin) A horny, water-insoluble protein found in the epidermis of vertebrates and in nails, feathers, hair, and horns.

ketone An organic molecule containing a carbonyl group bonded to two carbon atoms. Compare with *aldehyde*.

keystone species A species whose presence in an ecosystem largely determines the species composition and functioning of that ecosystem.

kidney The paired vertebrate organ important in excretion of metabolic wastes and in osmoregulation.

killer T cell See *T cytotoxic cell*.

kilobase (kb) 1000 bases or base pairs of a nucleic acid.

kilocalorie The amount of heat required to raise the temperature of 1 kg of water 1°C; also called *Calorie*, which is equivalent to 1000 calories.

kilojoule 1000 joules. See *joule*.

kinases Enzymes that catalyze the transfer of phosphate groups from ATP to acceptor molecules. See *protein kinases*. Compare with *phosphatases*.

kinesin See *microtubule-associated proteins (MAPs)*.

kinetic energy Energy of motion. Compare with *potential energy*.

kinetochore (kin-eh'-toh-kore) The portion of the chromosome centromere to which the mitotic spindle fibers attach.

kinetoplastid A single mitochondrion with an organized deposit of DNA; characteristic of trypanosomes.

kinocilium The single, long cilium that projects from the surface of a vertebrate hair cell.

kingdom A broad taxonomic category made up of related phyla; many biologists currently assign living organisms to five kingdoms and several "supergroups."

kin selection A type of natural selection that favors altruistic behavior toward relatives (kin), thereby ensuring that although the chances of an individual's survival are lessened, some of its genes will survive through successful reproduction of close relatives; increases inclusive fitness.

Klinefelter syndrome Inherited condition in which the affected individual is a sterile male with an XXY karyotype.

knockout mice Mouse strain in which both alleles of a gene are functionally disabled in one or more tissues by genetic engineering methods.

Koch's postulates A set of guidelines used to demonstrate that a specific pathogen causes specific disease symptoms.

Krebs cycle See *citric acid cycle*.

krummholz The gnarled, shrublike growth habit found in trees at high elevations, near their upper limit of distribution.

K-selected species See *K selection*.

labyrinth The system of interconnecting canals of the inner ear of vertebrates.

labyrinthodonts The first successful group of tetrapods.

lactate (lactic acid) A 3-carbon organic acid.

lactation (lak-tay'-shun) The production or release of milk from the breast.

lacteal (lak'-tee-al) One of the many lymphatic vessels in the intestinal villi that absorb fat.

lagging strand A strand of DNA that is synthesized as a series of short segments, called *Okazaki fragments*, which are then covalently joined by DNA ligase. Compare with *leading strand*.

lamins Polypeptides attached to the inner surface of the nuclear envelope that provide a type of skeletal framework.

lampreys Jawless freshwater and marine fishes with skeletons of cartilage, complete cranium, and rudimentary vertebrae.

landscape A large land area (several to many square kilometers) composed of interacting ecosystems.

landscape ecology The subdiscipline in ecology that studies the connections in a heterogeneous landscape.

large intestine The portion of the digestive tract of humans (and other vertebrates) consisting of the cecum, colon, rectum, and anus.

larva (pl., *larvae*) An immature form in the life history of some animals; may be unlike the parent.

larynx (lare'-inks) The organ at the upper end of the trachea that contains the vocal cords.

lateral line organ In fishes, a sensory organ that detects vibrations caused by waves and other movement in the water.

lateral meristems Areas of localized cell division on the side of a plant that give rise to secondary tissues. Lateral meristems, including the vascular cambium and the cork cambium, cause an increase in the girth of the plant body. Compare with *apical meristem*.

leaching The process by which dissolved materials are washed away or carried with water down through the various layers of the soil.

leader sequence Non-coding sequence of nucleotides in mRNA that is transcribed from the region that precedes (is upstream to) the coding region.

leading strand Strand of DNA that is synthesized continuously. Compare with *lagging strand*.

leaf scar Marks on a stem left when the petiole of a leaf breaks during abscission.

learning The process by which knowledge or skills are acquired as a result of experience; a change in the behavior of an animal that results from experience.

legume (leg'-yoom) (1) A simple, dry fruit that develops from a single carpel and splits open at maturity along two sutures to release seeds. (2) Any member of the pea family (e.g., pea, bean, peanut, alfalfa).

lek A small territory in which males compete for females.

lens The oval, transparent structure located behind the iris of the vertebrate eye; bends incoming light rays and brings them to a focus on the retina.

lenticels (len'-tih-sels) Porous swellings of cork cells in the stems of woody plants; facilitate the exchange of gases.

lepidosaurs (lep'-ih-do-sorz) A lineage of diapsid vertebrates that includes snakes, lizards, and tuataras.

leptin A hormone produced by adipose tissue that signals brain centers about the status of energy stores.

leukocytes (loo'-koh-sites) White blood cells; colorless amoeboid cells that defend the body against disease-causing organisms.

leukoplasts Colorless plastids; include amyloplasts, which are used for starch storage in cells of roots and tubers.

lichen (ly'-ken) A compound organism consisting of one or more symbiotic fungi and an alga or cyanobacterium.

life history traits Significant features of a species' life cycle, particularly traits that influence survival and reproduction.

lifespan The maximum duration of life for an individual of a species.

life table A table showing mortality and survival data by age of a population or cohort.

ligament (lig'-uh-ment) A connective tissue cable or strap that connects bones to each other or holds other organs in place.

ligand A molecule that binds to a specific site in a receptor or other protein.

ligand-gated channels See *ion channel-linked receptors*.

light-dependent reactions Reactions of photosynthesis in which light energy absorbed by chlorophyll is used to synthesize ATP and usually NADPH. Include *cyclic electron transport* and *noncyclic electron transport*.

light microscope (LM) Microscope in which light is refracted (bent) by glass lenses to produce a magnified image.

lignin (lig'-nin) A substance found in many plant cell walls that confers rigidity and strength, particularly in woody tissues.

limbic system In vertebrates, an action system of the brain. In humans, plays a role in emotional responses, motivation, sexual behavior, autonomic responses, and biological rhythms.

limiting resource An environmental resource that because it is scarce or unfavorable tends to restrict the ecological niche of an organism.

limnetic zone (lim-net'-ik) The open water away from the shore of a lake or pond extending down as far as sunlight penetrates. Compare with *littoral zone* and *profundal zone*.

linkage The tendency for a group of genes located on the same chromosome to be inherited together in successive generations.

linked genes See *linkage*.

lipase (lip'-ase) A fat-digesting enzyme.

lipid Any of a group of organic compounds that are insoluble in water but soluble in nonpolar solvents; lipids serve as energy storage and are important components of cell membranes.

lipoprotein (lip-oh-proh'-teen) A large molecular complex consisting of lipids and protein; transports lipids in the blood. High-density lipoproteins (HDLs) transport cholesterol to the liver; low-density lipoproteins (LDLs) deliver cholesterol to many cells of the body.

littoral zone (lit'-or-ul) The region of shallow water along the shore of a lake or pond. Compare with *limnetic zone* and *profundal zone*.

liver A large, complex organ that secretes bile, helps maintain homeostasis by removing or adding nutrients to the blood, and performs many other metabolic functions.

liverworts A phylum of spore-producing, nonvascular, thallose or leafy plants with a life cycle similar to that of mosses.

local hormones See *local regulators*.

local regulators Prostaglandins (a group of local hormones), growth factors, cytokines, and other soluble molecules that act on nearby cells by paracrine regulation or act on the cells that produce them (autocrine regulation).

locus (pl., *loci*) The place on the chromosome at which the gene for a given trait occurs (i.e., a segment of the chromosomal DNA containing information that controls some feature of the organism); also called *gene locus*.

logistic population growth Population growth that initially occurs at a constant rate of increase over time (i.e., exponential) but then levels out as the carrying capacity of the environment is approached. Compare with *exponential population growth*.

long-day plant A plant that flowers in response to shortening nights; also called *short-night plant*. Compare with *short-day*, *intermediate-day*, and *day-neutral plants*.

long-night plant See *short-day plant*.

long non-coding RNAs (lncRNAs) Molecules longer than 200 bases responsible for controlling genes by regulating chromatin structure.

long-term memory Memory that stores information for long periods of time; the hippocampus temporarily holds new information and helps place our experiences into categories so they can be consolidated and transferred to the cerebral cortex where they are stored along with similar memories. Compare with *short-term memory*.

long-term potentiation (LTP) Long-lasting increase in the strength of synaptic connections that occurs in response to a series of high-frequency electrical stimuli. Compare with *long-term synaptic depression (LTD)*.

long-term synaptic depression (LTD) Long-lasting decrease in the strength of synaptic connections that occurs in response to low-frequency stimulation of neurons. Compare with *long-term potentiation (LTP)*.

loop of Henle (hen'-lee) The U-shaped loop of a mammalian kidney tubule that extends down into the renal medulla.

loose connective tissue A type of connective tissue that is widely distributed in the body; consists of fibers strewn through a semifluid matrix.

lophophorates (lof-ah-for'ates) Members of three related invertebrate protostome phyla, characterized by a lophophore, a ciliated ring of tentacles that surrounds the mouth.

Lophotrochozoa A branch of the protostomes that includes the flatworms, nemerteans (proboscis worms), mollusks, annelids, and the lophophorate phyla.

low-density lipoprotein (LDL) See *lipoprotein*.

LUCA Acronym referring to the hypothesized last universal common ancestor of all living things on Earth today.

lumen (loo'-men) (1) The space enclosed by a membrane, such as the lumen of the endoplasmic reticulum or the thylakoid lumen. (2) The cavity or channel within a tube or tubular organ, such as a blood vessel or the digestive tract. (3) The space left within a plant cell after the cell's living material dies, as in tracheids.

lung An internal respiratory organ that functions in gas exchange; enables an animal to breathe air.

luteinizing hormone (LH) (loot'-eh-ny-zing) Gonadotropic hormone secreted by the anterior pituitary; stimulates ovulation and maintains the corpus luteum in the ovaries of females; stimulates testosterone production in the testes of males.

lymph (limf) The colorless fluid within the lymphatic vessels that is derived from blood plasma; contains white blood cells; ultimately lymph is returned to the blood.

lymphatic system A subsystem of the cardiovascular system; returns excess interstitial fluid (lymph) to the circulation; defends the body against disease organisms.

lymph node A mass of lymph tissue surrounded by a connective tissue capsule; manufactures lymphocytes and filters lymph.

lymphocyte (lim'-foh-site) White blood cell with nongranular cytoplasm that governs immune responses. See *B cell* and *T cell*.

lysis (ly'-sis) The process of disintegration of a cell or some other structure.

lysogenic conversion The change in properties of bacteria that results from the presence of a prophage.

lysogenic cycle (ly-so jen'-ik) A type of phage reproductive cycle in which the viral genome usually becomes integrated into the host DNA as a prophage; it is replicated along with the host DNA and does not kill the host cell. Compare with *lytic cycle*.

lysosomes (ly'-soh-sohmz) Intracellular organelles present in many animal cells; contain a variety of hydrolytic enzymes.

lysozyme An enzyme found in many tissues and in tears and other body fluids; attacks the cell wall of many gram-positive bacteria.

lytic cycle (lit'-ik) A type of phage reproductive cycle in which the release of phages from the bacterial cell results in rapid cell lysis (destruction). Compare with *lysogenic cycle*.

M phase That part of the cell cycle in which mitosis and cytokinesis occur.

macroevolution Large-scale evolutionary events over long time spans. Macroevolution results in phenotypic changes in populations that are significant enough to warrant their placement in taxonomic groups at the species level and higher. Compare with *microevolution*.

macromolecule A very large organic molecule, such as a protein or nucleic acid.

macronucleus A large nucleus found, along with one or several micronuclei, in ciliates. The macronucleus regulates metabolism and growth. Compare with *micronucleus*.

macronutrient An essential element required in fairly large amounts for normal growth. Compare with *micronutrient*.

macrophage (mak'-roh-faje) A large phagocytic cell capable of ingesting and digesting bacteria and cell debris. Macrophages are also antigen-presenting cells.

magnification The ratio of the size of an image as seen with a microscope to its actual size.

magnoliid One of the clades of flowering plants; magnoliids are core angiosperms that were traditionally classified as “dicots,” but molecular evidence indicates they are neither eudicots or monocots.

major histocompatibility complex (MHC) A large cluster of loci that encode the self-antigens present on the surface of most cells; these self-antigens are slightly different in each individual. The term refers to both the loci and to the self-antigens. Also see *human leukocyte antigen complex*.

malignant cells Cancer cells; tumor cells that are able to invade tissue and metastasize.

malignant transformation See *transformation*.

malnutrition Poor nutritional status; results from dietary intake that is either below or above required needs.

Malpighian tubules (mal-pig'-ee-an) The excretory organs of many arthropods.

mammals The class of vertebrates characterized by hair, mammary glands, a diaphragm, and differentiation of teeth.

mammary glands Exocrine glands that secrete milk for the young; a derived character of mammals.

mandible (man'-dih-bl) (1) The lower jaw of vertebrates. (2) Jawlike, external mouthparts of insects.

mangrove forest A tidal wetland dominated by mangrove trees in which the salinity fluctuates between that of sea water and fresh water.

mantle In the mollusk, a fold of tissue that covers the visceral mass and that usually produces a shell.

map unit A unit of a genetic map of a chromosome; 1% recombination between two loci equals one map unit.

marine snow The organic debris (plankton, dead organisms, fecal material, etc.) that “rains” into the dark area of the oceanic province from the lighted region above; the primary food of most organisms that live in the ocean's depths.

marsupials (mar-soo'-pee-ulz) A subclass of mammals, characterized by the presence of an abdominal pouch in which the young, which are born in a very undeveloped condition, are carried for some time after birth.

mass extinction The extinction of numerous species during a relatively short period of geologic time. Compare with *background extinction*.

mast cell A type of cell found in connective tissue; contains histamine and is important in an inflammatory response and in allergic reactions.

mate guarding The male guards his partner after copulation to ensure that she does not copulate with another male.

maternal effect genes Genes of the mother that are transcribed during oogenesis and subsequently affect the development of the embryo. Compare with *zygotic genes*.

matrix (may'-triks) (1) In cell biology, the interior of the compartment enclosed by the inner mitochondrial membrane. (2) In zoology, nonliving material secreted by and surrounding connective tissue cells; contains a network of microscopic fibers.

matter Anything that has mass and takes up space.

maxillae Appendages used for manipulating food; characteristic of crustaceans.

mechanical isolation A prezygotic reproductive isolating mechanism in which fusion of the gametes of two species is prevented by morphological or anatomical differences.

mechanoreceptor (meh-kan'-oh-ree-sep"-tor) A sensory cell or organ that perceives mechanical stimuli (e.g., touch, pressure, gravity, stretching, or movement).

medulla (meh-dul'-uh) (1) The inner part of an organ, such as the medulla of the kidney. Compare with *cortex*. (2) The most posterior part of the vertebrate brain, lying next to the spinal cord.

medusa A jellyfish-like animal; a free-swimming, umbrella-shaped stage in the life cycle of certain cnidarians. Compare with *polyp*.

megaphyll (meg'-uh-fil) Type of leaf found in horsetails, ferns, gymnosperms, and angiosperms; contains multiple vascular strands (i.e., complex venation). Compare with *microphyll*.

megasporangium (pl., *megasporangia*) In a heterosporous plant, structure in which megaspores are produced. Megasporangia of seed plants are *ovules* that develop into seeds following fertilization. Compare with *microsporangium*.

megaspore (meg'-uh-spor) The *n* spore in heterosporous plants that gives rise to a female gametophyte. Compare with *microspore*.

megasporocyte Cell within a megasporangium that undergoes meiosis to produce four *n* megaspores; also called *megaspore mother cell*. Compare with *microsporocyte*.

meiosis (my-oh'-sis) Process in which a *2n* cell undergoes two successive nuclear divisions (meiosis I and meiosis II), potentially producing four *n* nuclei; leads to the formation of gametes in animals and spores in plants.

meiosis I The first meiotic division; consists of prophase I, metaphase I, anaphase I, and telophase I; see *meiosis*.

meiosis II The second meiotic division; follows interkinesis and consists of prophase II, metaphase II, anaphase II, and telophase II; see *meiosis*.

melanin A dark pigment present in many animals; contributes to the color of the skin.

melanocortins A group of peptides that appear to suppress appetite, leading to weight loss.

melanocyte-stimulating hormones (MSH) See *melanocortins*.

melatonin (mel-ah-toh'-nin) A hormone secreted by the pineal gland that plays a role in setting circadian rhythms.

membrane potential A difference in electric charge between the two sides of a membrane.

memory The process of encoding, storing, and retrieving information or learned skills.

memory B cells B cells that continue to produce antibodies after the immune system overcomes an infection.

memory cells B or T cells (lymphocytes) that permit rapid mobilization of immune response on second or subsequent exposure to a particular antigen. See *memory B cells* and *memory T cells*.

memory T cells Cytotoxic or helper T cells that, after participating in an immune response, enter an inactive state until activated by exposure to the same type of antigen.

meninges (meh-nin'-jeez) (sing., *meninx*) The three membranes that protect the brain and spinal cord: the dura mater, arachnoid, and pia mater.

menopause The period (usually occurring between 45 and 55 years of age) in women when the recurring menstrual cycle ceases.

menstrual cycle (men'-stroo-ul) In the human female, the monthly sequence of events that prepares the body for pregnancy.

menstruation (men'-stroo-ay'-shun) The monthly discharge of blood and degenerated uterine lining in the human female; marks the beginning of each menstrual cycle.

meristem (mer'-ih-stem) A localized area of mitotic cell division in the plant body. See *apical meristem* and *lateral meristems*.

meroblastic cleavage Cleavage pattern observed in the telolecithal eggs of reptiles and birds, in which cleavage is restricted to a small disc of cytoplasm at the animal pole. Compare with *holoblastic cleavage*.

mesencephalon See *midbrain*.

mesenchyme (mes'-en-kime) A loose, often jellylike connective tissue containing undifferentiated cells; found in the embryos of vertebrates and the adults of some invertebrates.

mesentery (mez'-en-ter-ee) The peritoneum that connects the intestine to the posterior abdominal wall; thought to have an important role in maintaining health.

mesoderm (mez'-oh-derm) The middle germ layer of the early embryo; gives rise to connective tissue, muscle, bone, blood vessels, kidneys, and many other structures. Compare with *ectoderm* and *endoderm*.

mesoglea (mez-o-gee'-ah) Jellylike layer between the epidermis and gastrodermis in cnidarians and ctenophores.

mesophyll (mez'-oh-fil) Photosynthetic tissue in the interior of a leaf; sometimes differentiated into palisade mesophyll and spongy mesophyll.

Mesozoic era Span of geologic time commonly known as the Age of Reptiles; divided into Triassic (252–201 mya), Jurassic (201–145 mya), and Cretaceous (145–66 mya) periods; ended with the mass extinction of the dinosaurs and many other species.

messenger RNA (mRNA) RNA that specifies the amino acid sequence of a protein; transcribed from DNA.

metabolic pathway A series of chemical reactions in which the product of one reaction becomes the substrate of the next reaction.

metabolic rate Energy use by an organism per unit time. See *basal metabolic rate (BMR)*.

metabolic syndrome Condition that often precedes type 2 diabetes. Symptoms include obesity, large waist circumference, elevated blood glucose concentration, high triglyceride and low HDL (“good” cholesterol) concentrations, and high blood pressure.

metabolism The sum of all the chemical processes that occur within a cell or organism; the transformations by which energy and matter are made available for use by the organism. See *anabolism* and *catabolism*.

metabolism first hypothesis An explanation of the origin of life, in which life began as a self-sustaining, organized system consisting of chemical reactions between simple molecules enclosed within a boundary.

metamorphosis (met’-ah-mor’-fuh-sis) Transition from one developmental stage to another, such as from a larva to an adult. See also *complete metamorphosis* and *incomplete metamorphosis*.

metanephridia (sing., *metanephridium*) The excretory organs of annelids and mollusks; each consists of a tubule open at both ends; at one end a ciliated funnel opens into the coelom, and the other end opens to the outside of the body.

metaphase (met’-ah-faze) The stage of mitosis in which the chromosomes line up on the midplane of the cell (metaphase plate). Occurs after prometaphase and before anaphase.

metaphase I See *meiosis* and *meiosis I*.

metaphase II See *meiosis* and *meiosis II*.

metaphase plate See *metaphase*.

metapopulation A population that is divided into several local populations among which individuals occasionally disperse.

metarterioles Small blood vessels that directly link arterioles with venules.

metastasis (met-tas’-tuh-sis) The spreading of cancer cells from one organ or part of the body to another.

metencephalon Part of the vertebrate embryonic brain; gives rise to the cerebellum and pons.

methanogens (meth-an’-o-jens) Archaeons that inhabit oxygen-free environments, are obligate anaerobes, and produce methane, an important greenhouse gas.

methyl group A nonpolar functional group; abbreviated $-CH_3$.

microbiome A community of microorganisms, including their genomes and all their interactions.

microbiota A community of microorganisms that inhabits a particular organism.

microclimate Local variations in climate produced by differences in elevation, in the steepness and direction of slopes, and in exposure to prevailing winds.

microevolution Small-scale evolutionary change caused by changes in allele or genotype frequencies that occur within a population over a few generations. Compare with *macroevolution*.

microfilaments Thin fibers consisting of actin protein subunits; form part of the cytoskeleton.

microfossils Ancient traces (fossils) of microscopic life.

microglia Phagocytic glial cells found in the CNS.

micronucleus One or more smaller nuclei found, along with the macronucleus, in ciliates. The micronucleus is involved in sexual reproduction. Compare with *macronucleus*.

micronutrient An essential element that is required in trace amounts for normal growth. Compare with *macronutrient*.

microphyll (mi’-kro-fil) Type of leaf found in club mosses; contains one vascular strand (i.e., simple venation). Compare with *megaphyll*.

microRNA (miRNA) Single-stranded RNA molecules about 22 nucleotides in length that control the expression of genes at the posttranscriptional level by binding mRNA molecules with base sequences complementary to the miRNA, blocking translation of the mRNA or causing it to be degraded. Also involved in control of transcription of some genes. See also *RNA interference (RNAi)*.

microsphere A protobiont produced by adding water to abiotically formed polypeptides.

microsporangium (pl., *microsporangia*) In a heterosporous plant, structure in which microspores are produced; compare with *megasporangium*.

microspore (mi’-kro-spor) The *n* spore in heterosporous plants that gives rise to a male gametophyte. Compare with *megaspore*.

microsporocyte Cell within a microsporangium that undergoes meiosis to produce four *n* microspores; also called *microspore mother cell*. Compare with *megasporeocyte*.

microsporidia Small, unicellular, fungal parasites that infect eukaryotic cells; classified with the zygomycetes.

microtubule-associated proteins (MAPs) Structural proteins that help regulate microtubule assembly and cross-link microtubules to other cytoskeletal polymers; and motors, such as kinesin and dynein, that use ATP to produce movement.

microtubule-organizing center (MTOC) The region of the cell from which microtubules are anchored and possibly assembled. The MTOCs of many organisms (including animals, but not flowering plants or most gymnosperms) contain a pair of centrioles.

microtubules (my-kroh-too’-bewls) Hollow, cylindrical fibers consisting of tubulin protein subunits; major components of the cytoskeleton and found in mitotic spindles, cilia, flagella, centrioles, and basal bodies.

microvilli (sing., *microvillus*) Minute projections of the plasma membrane that increase the surface area of the cell; found mainly in cells concerned with absorption or secretion, such as those lining the intestine or the kidney tubules.

midbrain In vertebrate embryos, one of the three divisions of the developing brain. Also called *mesencephalon*. Compare with *forebrain* and *hindbrain*.

middle lamella The layer composed of pectin polysaccharides that serves to cement together the primary cell walls of adjacent plant cells.

midvein The main, or central, vein of a leaf.

migration (1) The periodic or seasonal movement of an organism (individual or population) from one place to another, usually over a long distance.

See *dispersal*. (2) In evolutionary biology, a movement of individuals that results in a transfer of alleles from one population to another. See *gene flow*.

mineralocorticoids (min’-ur-al-oh-kor’-tih-koidz) Hormones produced by the adrenal cortex that regulate mineral metabolism and, indirectly, fluid balance. The principal mineralocorticoid is aldosterone.

minerals Inorganic nutrients ingested as salts dissolved in food and water.

minimum viable population (MVP) The smallest population size at which a species has a high chance of sustaining its numbers and surviving into the future.

mismatch repair A DNA repair mechanism in which special enzymes recognize the incorrectly paired nucleotides and remove them. DNA polymerases then fill in the missing nucleotides.

missense mutation A type of base-pair substitution mutation that causes one amino acid to be substituted for another in the resulting protein product. Compare with *nonsense mutation*.

mitochondria (my’-toh-kon’-dree-ah) (sing., *mitochondrion*) Intracellular organelles that are the sites of oxidative phosphorylation in eukaryotes; include an outer membrane and an inner membrane.

mitochondrial DNA (mtDNA) DNA present in mitochondria that is transmitted maternally, from mothers to their offspring. Mitochondrial DNA mutates more rapidly than nuclear DNA.

mitosis (my-toh’-sis) The division of the cell nucleus resulting in two daughter nuclei, each with the same number of chromosomes as the parent nucleus; mitosis consists of prophase, prometaphase, metaphase, anaphase, and telophase. Cytokinesis usually overlaps the telophase stage.

mitotic spindle Structure consisting mainly of microtubules that provides the framework for chromosome movement during cell division.

mitral valve See *atrioventricular valve*.

mobile genetic element See *transposon*.

model organism A species chosen for biological studies because it has characteristics that allow for the efficient analysis of biological processes. Most model organisms are small, have short generation times, and are easy to grow and study under controlled conditions.

modern synthesis A comprehensive, unified explanation of evolution based on combining previous scientific theories, especially of Mendelian genetics with Darwin’s scientific theory of evolution by natural selection.

molars Posterior teeth of a mammal; flattened for crushing and grinding; compare with *incisors*, *canines*, and *premolars*.

mole The atomic mass of an element or the molecular mass of a compound, expressed in grams; one mole of any substance has 6.02×10^{23} units (Avogadro’s number).

molecular anthropology The branch of science that compares genetic material from individuals of regional human populations to help unravel the origin and migrations of modern humans.

molecular chaperones Proteins that help other proteins fold properly. Although chaperones do not dictate the folding pattern, they make the process more efficient.

molecular clock analysis A comparison of the DNA nucleotide sequences of related organisms to estimate when they diverged from one another during the course of evolution.

molecular formula The type of chemical formula that gives the actual numbers of each type of atom in a molecule. Compare with *simplest formula* and *structural formula*.

molecular mass The sum of the atomic masses of the atoms that make up a single molecule of a compound; expressed in atomic mass units (amu) or daltons.

molecular systematics The science that focuses on molecular structure to clarify evolutionary relationships.

molecule The smallest particle of a covalently bonded element or compound; two or more atoms joined by covalent bonds.

mollusks A phylum of coelomate protostome animals characterized by a soft body, visceral mass, mantle, and foot.

molting The shedding and replacement of an outer covering such as an exoskeleton.

molting hormone A steroid hormone that stimulates growth and molting in insects. Also called *ecdysone*.

monoacylglycerol (mon"-o-as-il-glis'-er-ol) Lipid consisting of glycerol combined chemically with a single fatty acid. Also called *monoglyceride*. Compare with *diacylglycerol* and *triacylglycerol*.

monoclonal antibodies Identical antibody molecules produced by cells cloned from a single cell.

monocot (mon'-oh-kot) One of two classes of flowering plants; monocot seeds contain a single cotyledon, or seed leaf. Compare with *eudicot*.

monocyte (mon'-oh-site) A type of white blood cell; a large, phagocytic, nongranular leukocyte that enters the tissues and differentiates into a macrophage.

monoecious (mon-ee'-shus) Having male and female reproductive parts in separate flowers or cones on the same plant; compare with *dioecious*.

monogamy A mating system in which a male animal mates with a single female during a breeding season.

monoglyceride See *monoacylglycerol*.

monohybrid cross A genetic cross that takes into account the behavior of alleles of a single locus. Compare with *dihybrid cross*.

monokaryotic (mon"-o-kare-ee-ot'-ik) The condition of having a single *n* nucleus per cell, characteristic of certain fungal hyphae. Compare with *dikaryotic*.

monomer (mon'-oh-mer) A molecule that can link with other similar molecules; two monomers join to form a dimer, whereas many form a polymer. Monomers are small (e.g., sugars or amino acids) or large (e.g., tubulin or actin proteins).

monophyletic group (mon"-oh-fye-let'-ik) A group of organisms that includes a recent common ancestor and all its descendants; a clade. Compare with *polyphyletic group* and *paraphyletic group*.

monosaccharide (mon-oh-sak'-ah-ride) A sugar that cannot be degraded by hydrolysis to a simpler sugar (e.g., glucose or fructose).

monosomy A type of aneuploidy in which an individual lacks one member of a pair of chromosomes; designated $2n - 1$.

monotremes (mon'-oh-treemz) Egg-laying mammals such as the duck-billed platypus of Australia.

monounsaturated fatty acid See *fatty acid*.

monozygotic twins Genetically identical twins that arise from the division of a single fertilized egg; commonly known as *identical twins*. Compare with *dizygotic twins*.

Montreal Protocol International agreement designed to protect the ozone layer by gradually eliminating the production of ozone-depleting substances.

morphogen Any chemical agent thought to govern the processes of cell differentiation and pattern formation that lead to morphogenesis.

morphogenesis (mor-foh-jen'-eh-sis) The development of the form and structures of an organism and its parts; proceeds through a series of steps known as *pattern formation*.

mortality The rate at which individuals die; the average per capita death rate.

morula (mor'-yoo-lah) An early embryo consisting of a solid ball of cells.

mosaic development A rigid developmental pattern in which the fates of cells become restricted early in development. Compare with *regulative development*.

mosses A phylum of spore-producing nonvascular plants with an alternation of generations in which the dominant *n* gametophyte alternates with a $2n$ sporophyte that remains attached to the gametophyte.

motor neuron An efferent neuron that transmits impulses away from the central nervous system to skeletal muscle.

motor program A coordinated sequence of muscle actions responsible for many behaviors we think of as automatic.

motor unit Functional unit consisting of a single motor neuron and the muscle fibers it innervates.

mRNA cap An unusual nucleotide, 7-methylguanylate, that is added to the 5' end of a eukaryotic messenger RNA. Capping enables eukaryotic ribosomes to bind to mRNA.

mucosa (mew-koh'-suh) See *mucous membrane*.

mucous membrane A type of epithelial membrane that lines a body cavity that opens to the outside of the body (e.g., the digestive and respiratory tracts); also called *mucosa*.

mucus (mew'-cus) A sticky secretion composed of covalently linked protein and carbohydrate; serves to lubricate body parts and trap particles of dirt and other contaminants. (The adjectival form is spelled *mucous*.)

Müllerian mimicry (mul-ler'-ee-un mim'-ih-kree) The resemblance of dangerous, unpalatable, or poisonous species to one another so that potential predators recognize them more easily. Compare with *Batesian mimicry*.

multiple alleles (al-leelz') Three or more alleles of a single locus (in a population), such as the alleles governing the ABO series of blood types.

multiple fruit A fruit that develops from many ovaries of many separate flowers (e.g., pineapple). Compare with *simple*, *aggregate*, and *accessory fruits*.

muscle (1) A tissue specialized for contraction. (2) An organ that produces movement by contraction.

muscle fibers Muscle cells; elongated cells that contain myofibrils, the contractile units.

muscle spindles Proprioceptors that detect muscle movement.

muscle tone The continuous, partial contraction of individual muscles and muscle groups.

mutagen (mew'-tah-jen) Any agent capable of entering the cell and producing mutations.

mutation Any change in DNA; may include a change in the nucleotide base pairs of a gene, a rearrangement of genes within the chromosomes so that their interactions produce different effects, or a change in the chromosomes themselves.

mutualism In ecology, a symbiotic relationship in which both partners benefit from the association. Compare with *parasitism* and *commensalism*.

mycelium (my-seel'-ee-um) (pl., *mycelia*) The vegetative body of most fungi and certain protists (water molds); consists of a branched network of hyphae.

mycology The study of fungi.

mycorrhizae (my'-kor-rye'-zee) Mutualistic associations of fungi and plant roots that aid in the plant's absorption of essential minerals from the soil. Hyphae of ectomycorrhizal fungi coat plant roots; those of endomycorrhizal fungi penetrate plant cell walls (see *arbuscules*).

mycotoxins Poisonous chemical compounds produced by fungi (e.g., aflatoxins that harm the liver and are known carcinogens).

myelencephalon Part of the vertebrate embryonic brain; gives rise to the medulla.

myelin sheath (my'-eh-lin) The white, fatty material that forms a sheath around the axons of certain nerve cells, which are then called *myelinated fibers*.

myocardial infarction (MI) Heart attack; serious consequence occurring when the heart muscle receives insufficient oxygen.

myofibrils (my-oh-fy'-brilz) Tiny threadlike structures in the cytoplasm of striated and cardiac muscle that are composed of myosin filaments and actin filaments; these filaments are responsible for muscle contraction; see *myosin filaments* and *actin filaments*.

myofibril See *myofibril*.

myoglobin (my'-oh-glo'-bin) A hemoglobin-like, oxygen-transferring protein found in muscle.

myosin (my'-oh-sin) A protein that together with actin is responsible for muscle contraction.

myosin filaments Thick filaments consisting mainly of the protein myosin; actin and myosin filaments make up the myofibrils of muscle fibers.

myxedema Hypothyroid condition in which there is almost no thyroid function, characterized by slowing down of physical and mental activity.

n The chromosome number of a gamete. The chromosome number of a zygote is $2n$. If an organism is not polyploid, the *n* gametes are haploid and the $2n$ zygotes are diploid.

NAD⁺/NADH Oxidized and reduced forms, respectively, of nicotinamide adenine dinucleotide, a coenzyme that transfers electrons (as hydrogen), particularly in catabolic pathways, including cellular respiration.

NADP⁺/NADPH Oxidized and reduced forms, respectively, of nicotinamide adenine dinucleotide phosphate, a coenzyme that acts as an electron (hydrogen) transfer agent, particularly in anabolic pathways, including photosynthesis.

nanoplankton Extremely minute (<10 μm in length) algae that are major producers in the ocean because of their great abundance; part of phytoplankton.

natality The rate at which individuals produce offspring; the average per capita birth rate.

national conservation strategy Detailed plan for managing and preserving the biological diversity of a specific country.

natural killer cell (NK cell) A large, granular lymphocyte that functions in both nonspecific and specific immune responses; releases cytokines and proteolytic enzymes that target tumor cells and cells infected with viruses and other pathogens.

natural selection The mechanism of evolution proposed by Charles Darwin; the tendency of organisms that have favorable adaptations to their environment to survive and become the parents of the next generation. Evolution occurs when natural selection results in changes in allele frequencies in a population. Compare with *artificial selection*.

navigation Involves the use of cues to change direction when necessary in order to reach a specific destination; requires a sense of direction, called compass sense, and an awareness of location, called map sense.

Neandertals See *Homo neanderthalensis*.

necrosis Uncontrolled cell death that causes inflammation and damages other cells. Compare with *apoptosis*.

nectary (nek'-ter-ee) In plants, a gland or other structure that secretes nectar.

negative control A genetic control system in which a regulatory protein binds to DNA, turning off transcription of a gene. Compare with *positive control*.

negative feedback system A regulatory system in which a change in some steady state triggers a response that counteracts, or reverses, the change, restoring homeostasis (e.g., how mammals maintain body temperature). Compare with *positive feedback system*.

nekton (nek'-ton) Free-swimming aquatic organisms such as fish and turtles. Compare with *plankton*.

nematocyst (nem-at'-oh-sist) A stinging structure found within cnidocytes (stinging cells) in cnidarians; used for anchorage, defense, and capturing prey.

nematodes The phylum of animals commonly known as *roundworms*.

nemerteans The phylum of animals commonly known as *ribbon worms*; each has a proboscis (tubular feeding organ) for capturing prey.

Neogene period See *Cenozoic era*.

neonate Newborn individual.

neoplasm See *tumor*.

nephridial organ (neh-frid'-ee-al) The excretory organ of many invertebrates; consists of simple or

branching tubes that usually open to the outside of the body through pores; also called *nephridium*.

nephron (nef'-ron) The functional, microscopic unit of the vertebrate kidney.

neritic province (ner-ih'-tik) Ocean water that extends from the shoreline to where the bottom reaches a depth of 200 m. Compare with *oceanic province*.

nerve A bundle of axons (or dendrites) wrapped in connective tissue that conveys impulses between the central nervous system and some other part of the body.

nerve cord A bundle of nerves that extends from a central ganglion or brain and gives rise to smaller nerves. In vertebrates the nerve cord is dorsal and tubular.

nerve net The network of neurons found in cnidarians and ctenophores.

nervous system In most invertebrates, consists of ganglia, sensory cells or sense organs, and networks of neurons. In vertebrates, consists of the brain, spinal cord, sense organs, and nerves; the body's main regulatory system.

nervous tissue A type of animal tissue specialized for transmitting electrical and chemical signals.

net primary productivity (NPP) The energy that remains in an ecosystem (as biomass) after cellular respiration has occurred; net primary productivity equals gross primary productivity minus respiration. Compare with *gross primary productivity (GPP)*.

neural circuit A functional group of neurons, typically consisting of one or more afferent neurons, one or more interneurons, and one or more efferent neurons.

neural crest cells (noor'-ul) A group of embryonic cells found only in vertebrates; develop along the neural tube and migrate to various parts of the embryo where they give rise to (or influence the development of) nerves, head muscles, cranium, jaws, and other structures.

neural plasticity The ability of the nervous system to change in response to experience.

neural plate See *neural tube*.

neural signaling The transmission of information by neurons (nerve cells).

neural transmission The conduction of a neural impulse, or action potential, along a neuron or from one neuron to another.

neural tube The hollow, longitudinal structure in the early vertebrate embryo that gives rise to the brain and spinal cord. The neural tube forms from the neural plate, a flattened, thickened region of the ectoderm that rolls up and sinks below the surface.

neuroendocrine cells Neurons that produce neurohormones.

neuroendocrine signaling Neuroendocrine cells produce neurohormones that are transported down axons and released into the interstitial fluid.

neurofibrillary tangles Abnormal fibrous deposits in the cytoplasm of neurons in the brains of individuals with Alzheimer's disease; interfere with neural signaling.

neurogenesis The production of new neurons.

neurohormones Hormones produced by neuroendocrine cells; transported down axons and released into interstitial fluid; common in

invertebrates; in vertebrates, the hypothalamus produces neurohormones.

neuron (noor'-on) A nerve cell; a conducting cell of the nervous system that typically consists of a cell body, dendrites, and an axon.

neuropeptide One of a group of peptides produced in neural tissue that function as signaling molecules; many are neurotransmitters.

neuropeptide Y (NPY) A signaling molecule produced by the hypothalamus that stimulates appetite and slows metabolism; helps restore energy homeostasis when leptin levels and food intake are low.

neurotransmitters Chemical signals used by neurons to transmit impulses across a synapse.

neutral solution A solution of pH 7; there are equal concentrations of hydrogen ions [H⁺] and hydroxide ions [OH⁻]. Compare with *acidic solution* and *basic solution*.

neutral variation Variation that does not appear to confer any selective advantage or disadvantage to the organism.

neutron (noo'-tron) An electrically neutral particle with a mass of 1 atomic mass unit (amu) found in the atomic nucleus. Compare with *proton* and *electron*.

neutrophil (new'-truh-fil) A type of granular leukocyte important in immune responses; a type of phagocyte that engulfs and destroys bacteria and foreign matter.

niche (nich) The totality of an organism's adaptations, its use of resources, and the lifestyle to which it is fitted in its community; how an organism uses materials in its environment as well as how it interacts with other organisms; also called *ecological niche*. See *fundamental niche* and *realized niche*.

nicotinamide adenine dinucleotide See *NAD⁺/NADH*.

nicotinamide adenine dinucleotide phosphate See *NADP⁺/NADPH*.

nitric oxide (NO) A gaseous signaling molecule; a neurotransmitter.

nitrification (nie'-tra-fuh-kay'-shun) The conversion of ammonia (NH₃) to nitrate (NO₃⁻) by certain bacteria (nitrifying bacteria) in the soil; part of the nitrogen cycle.

nitrogenase (nie-traa'-jen-ase) The enzyme responsible for nitrogen fixation under anaerobic conditions.

nitrogen cycle The worldwide circulation of nitrogen from the abiotic environment into living things and back into the abiotic environment.

nitrogen fixation The conversion of atmospheric nitrogen (N₂) to ammonia (NH₃) by certain bacteria; part of the nitrogen cycle.

nitrogen oxides Binary compounds of oxygen and nitrogen, produced by combustion, that are a necessary ingredient in photochemical smog.

nociceptors (no'-sih-sep-torz) Pain receptors; free endings of certain sensory neurons whose stimulation is perceived as pain.

nocturnal animals Animals that are most active at night. Compare with *crepuscular animals* and *diurnal animals*.

node The area on a stem where each leaf is attached. Compare with *internode*.

nodes of Ranvier (ron'-ve-a) Gaps in the myelin sheath of myelinated neurons where an action potential can be generated. In saltatory conduction, the action potential appears to "leap" along from one node of Ranvier to the next.

nodules Swellings on the roots of plants, such as legumes, in which symbiotic nitrogen-fixing bacteria (*rhizobia*) live.

noncompetitive inhibition The binding of a substance (the noncompetitive inhibitor) to a site other than the active site of an enzyme, thereby lowering the rate at which the enzyme catalyzes a reaction. Compare with *competitive inhibition*.

noncompetitive inhibitor See *noncompetitive inhibition*.

noncyclic electron transport In photosynthesis, the linear flow of electrons, produced by photolysis of water, through photosystems II and I; results in the formation of ATP (by chemiosmosis), NADPH, and O₂. Compare with *cyclic electron transport*.

nondisjunction Abnormal separation of sister chromatids or of homologous chromosomes caused by their failure to disjoin (move apart) properly during mitosis or meiosis.

nonpolar covalent bond Chemical bond formed by the equal sharing of electrons between atoms of approximately equal electronegativity. Compare with *polar covalent bond*.

nonpolar molecule Molecule that does not have a positively charged end and a negatively charged end; nonpolar molecules are generally insoluble in water. Compare with *polar molecule*.

nonsense mutation A base-pair substitution mutation that results in an amino acid-specifying codon being changed to a termination (stop) codon; when the abnormal mRNA is translated, the resulting protein is usually shortened and nonfunctional. Compare with *missense mutation*.

nonspecific immune responses See *innate immune responses*.

nonspecific immunity See *innate immune responses*.

norepinephrine (nor-ep-ih-nef'-rin) A neurotransmitter that is also a hormone secreted by the adrenal medulla.

norm of reaction The range of phenotypic possibilities that can develop from a single genotype under different environmental conditions.

Northern blot A technique in which RNA fragments, previously separated by gel electrophoresis, are transferred to a nitrocellulose membrane and detected by autoradiography or chemical luminescence. Compare with *Southern blot* and *Western blot*.

notochord (no'-toe-kord) The flexible, longitudinal rod in the anterior-posterior axis that serves as an internal skeleton in the embryos of all chordates and in the adults of some.

nuclear area Region of a prokaryotic cell that contains DNA; not enclosed by a membrane. Also called *nucleoid*.

nuclear envelope The double membrane system that encloses the cell nucleus of eukaryotes.

nuclear equivalence The concept that the nuclei of all differentiated cells of an adult organism are genetically identical to one another and to the nucleus of the zygote from which they were derived. Compare with *genomic rearrangement* and *gene amplification*.

nuclear pores Structures in the nuclear envelope that allow passage of certain materials between the cell nucleus and the cytoplasm.

nucleoid See *nuclear area*.

nucleolus (new-klee'-oh-lus) (pl., *nucleoli*) Specialized structure in the cell nucleus formed from regions of several chromosomes; site of assembly of the ribosomal subunits.

nucleoplasm The contents of the cell nucleus.

nucleoside triphosphate Molecule consisting of a nitrogenous base, a pentose sugar, and three phosphate groups (e.g., adenosine triphosphate [ATP]).

nucleosomes (new'-klee-oh-sohmz) Repeating units of chromatin structure, each consisting of a length of DNA wound around a complex of eight histone molecules. Adjacent nucleosomes are connected by a DNA linker region associated with another histone protein.

nucleotide (noo'-klee-oh-tide) A molecule consisting of one or more phosphate groups, a 5-carbon sugar (ribose or deoxyribose), and a nitrogenous base (purine or pyrimidine).

nucleotide excision repair A DNA repair mechanism commonly used to repair a damaged segment of DNA caused by the sun's ultraviolet radiation or by harmful chemicals.

nucleus (new'-klee-us) (pl., *nuclei*) (1) The central region of an atom that contains the protons and neutrons. (2) A cell organelle in eukaryotes that contains the DNA and serves as the control center of the cell. (3) A mass of nerve cell bodies in the central nervous system. Compare with *ganglion*.

nut A simple, dry fruit that contains a single seed and is surrounded by a hard fruit wall.

nutrients The chemical substances in food that are used as components for synthesizing needed materials and/or as energy sources.

nutrition The process of taking in and using food (nutrients).

obesity Excess accumulation of body fat; a person is considered obese if the body mass index (BMI) is 30 or higher.

obligate anaerobe An organism that grows only in the absence of oxygen. Compare with *facultative anaerobe*.

occipital lobes Posterior areas of the mammalian cerebrum; interpret visual stimuli from the retina of the eye.

ocean currents Mass movements of surface ocean water produced by winds blowing over the ocean.

oceanic province That part of the open ocean that overlies an ocean bottom deeper than 200 m. Compare with *neritic province*.

Okazaki fragment One of many short segments of DNA, each 100 to 1000 nucleotides long, that must be joined by DNA ligase to form the lagging strand in DNA replication.

olfactory bulbs Olfactory relay centers where axons from the olfactory nerves transmit information to neurons that signal higher centers.

olfactory epithelium Tissue containing odor-sensing neurons.

olfactory nerve The first cranial nerve; consists of the axons of the olfactory receptor cells and extends to the olfactory bulb in the brain.

oligodendrocyte A type of glial cell that forms myelin sheaths around neurons in the CNS.

omega-3 fatty acids Essential fatty acids found in salmon and other fatty fishes, walnuts, and certain vegetable oils (e.g., canola, soybean); studies suggest that omega-3 fatty acids help lower triglycerides and blood pressure, and have other health benefits.

ommatidium (om"-ah-tid'-ee-um) (pl., *ommatidia*) One of the light-detecting units of a compound eye, consisting of a lens and a crystalline cone that focus light onto photoreceptors called *retinular cells*.

omnivore (om'-nih-vore) An animal that eats a variety of plant and animal materials.

oncogene (on'-koh-jeen) An abnormally functioning gene implicated in causing cancer. Compare with *proto-oncogene* and *tumor suppressor gene*.

1000 Genomes Project An international collaborative initiative completed in 2012 to provide a detailed catalogue of human genetic variation by determining the genomic DNA sequences of over 1000 anonymous individuals from a number of different ethnic groups. Compare with *Human Genome Project*.

oocytes (oh'-oh-sites) Meiotic cells that give rise to egg cells (ova).

oogamy (oh-og'-uh-me) The fertilization of a large, nonmotile female gamete by a small, motile male gamete. Compare with *isogamy* and *anisogamy*.

oogenesis (oh"-oh-jen'-eh-sis) Production of female gametes (eggs) by meiosis. Compare with *spermatogenesis*.

oogonia Undifferentiated cells in the ovaries that give rise to primary oocytes.

oospore A thick-walled, resistant spore formed from a zygote during sexual reproduction in water molds.

open circulatory system A type of circulatory system in which the blood bathes the tissues directly; characteristic of arthropods and many mollusks. Compare with *closed circulatory system*.

open system An entity that exchanges energy with its surroundings. Compare with *closed system*.

operant conditioning A type of learning in which an animal is rewarded or punished for performing a behavior it discovers by chance.

operator site One of the control regions of an operon; the DNA segment to which a repressor binds, thereby inhibiting the transcription of the adjacent structural genes of the operon.

operculum In bony fishes, a protective flap of the body wall that covers the gills.

operon (op'-er-on) In prokaryotes, a group of structural genes that are coordinately controlled and transcribed as a single message, plus their adjacent regulatory elements.

opisthokonts Members of the unikont clade in which motile cells possess a single posterior flagellum; include fungi, choanoflagellates, and animals. Compare with *amoebozoa*.

opposable thumb The arrangement of the fingers so that they are positioned opposite the thumb, enabling the organism to grasp objects.

optic chiasm The X-shaped structure formed by the crossing of the optic nerves in the floor of the hypothalamus.

optic nerve The second cranial nerve; transmits visual information from the retina to the brain; composed of the axons of ganglion cells.

optimal foraging The process of obtaining food in a manner that maximizes benefits and/or minimizes costs.

orbital Region in which electrons occur in an atom or molecule.

orbital hybridization A rearrangement of the orbitals in the valence shell that may occur when an atom forms covalent bonds with other atoms.

order A taxonomic category made up of related families.

Ordovician period See *Paleozoic era*.

organ A specialized structure, such as the heart or liver, or a flower, made up of tissues and adapted to perform a specific function or group of functions.

organelle One of the specialized structures within the cell, such as the mitochondria, Golgi complex, ribosomes, or contractile vacuole; many organelles are membrane-enclosed.

organic compound A compound consisting of a backbone made up of carbon atoms. Compare with *inorganic compound*.

organism Any living system consisting of one or more cells.

organismic model Cooperative view of community, described by Clements, in which a community goes through certain stages of development (succession), like the embryonic stages of an organism, and eventually reaches an adult state (climax community). Compare with *individualistic model*.

organismic respiration See *respiration*.

organ of Corti The structure within the inner ear of vertebrates that contains receptor cells that sense sound vibrations.

organogenesis The process of organ formation.

organ system An organized group of tissues and organs that work together to perform a specialized set of functions (e.g., the digestive system or circulatory system).

orgasm (or'-gazm) The climax of sexual excitement.

origin of replication A specific site on the DNA where replication begins.

orthologous genes Homologous genes found in different species because they were inherited from a common ancestor.

osculum (os'kyuh-lum) In a sponge, the main opening between the spongocoel and the external environment.

osmoconformer An animal in which the salt concentration of body fluids varies along with changes in the surrounding sea water so that it stays in osmotic equilibrium with its surroundings. Compare with *osmoregulator*.

osmolarity The number of osmoles of solute per liter of solution. See *osmole*.

osmole The number of solute particles (molecules or ions) produced when a mole of solute dissolves. One mole of glucose is one osmol; one mole of sodium chloride (NaCl), which dissolves to give two types of particles, is two osmoles.

osmoregulation (oz"-moh-reg-yoo-lay'-shun) The active regulation of the osmotic pressure of body fluids so that they do not become excessively dilute or excessively concentrated.

osmoregulator An animal that maintains an optimal salt concentration in its body fluids despite

changes in salinity of its surroundings. Compare with *osmoconformer*.

osmosis (oz-moh'-sis) The net movement of water (the principal solvent in biological systems) by diffusion through a selectively permeable membrane from a region of higher concentration of water (a hypotonic solution) to a region of lower concentration of water (a hypertonic solution).

osmotic pressure The pressure that must be exerted on the hypertonic side of a selectively permeable membrane to prevent diffusion of water (by osmosis) from the side containing pure water.

osteichthyes (os"-tee-ick'-thees) Historically, the vertebrate class of bony fishes. Biologists now divide bony fishes into three classes: Actinopterygii, the ray-finned fishes; Actinistia, the lobe-finned fishes; and Dipnoi, the lungfishes.

osteoblast (os'-tee-oh-blast) A type of bone cell that secretes the protein matrix of bone. Also see *osteocyte*.

osteoclast (os'-tee-oh-clast) Large, multinucleate cell that helps sculpt and remodel bones by dissolving and removing part of the bony substance.

osteocyte (os'-tee-oh-site) A mature bone cell; an osteoblast that has become embedded within the bone matrix and occupies a lacuna.

osteon (os'-tee-on) The spindle-shaped unit of bone composed of concentric layers of osteocytes organized around a central Haversian canal containing blood vessels and nerves.

otoliths (oh'-toe-liths) Small calcium carbonate crystals in the saccule and utricle of the inner ear; sense gravity and are important in static equilibrium.

outbreeding The mating of individuals of unrelated strains, also called *outcrossing*. Compare with *inbreeding*.

outcrossing See *outbreeding*.

outgroup In cladistics, a taxon that represents an approximation of the ancestral condition; the outgroup is related to the *ingroup* (the members of the group under study) but separated from the ingroup lineage before they diversified.

ovary (oh'-var-ee) (1) In animals, one of the paired female gonads responsible for producing eggs and sex hormones. (2) In flowering plants, the base of the carpel that contains ovules; ovaries develop into fruits after fertilization.

oviduct (oh'-vih-dukt) The tube that carries ova from the ovary to the uterus, cloaca, or body exterior. Also called *fallopian tube* or *uterine tube*.

oviparous (oh-vip'-ur-us) Bearing young in the egg stage of development; egg laying. Compare with *viviparous* and *ovoviviparous*.

ovoviviparous (oh"-voh-vih-vip'-ur-us) A type of development in which the young hatch from eggs incubated inside the mother's body. Compare with *viviparous* and *oviparous*.

ovulation (ov-u-lay'-shun) The release of an egg from the ovary.

ovule (ov'-yool) The structure in the plant ovary that develops into the seed following fertilization; also called *megasporangium*.

ovum (pl., *ova*) Female gamete of an animal.

oxaloacetate A 4-carbon compound; an important intermediate in the citric acid cycle and in the

C₄ and CAM pathways of carbon fixation in photosynthesis.

oxidants Highly reactive molecules such as free radicals, peroxides, and superoxides that are produced during normal cell processes that require oxygen; can damage DNA and other molecules by snatching electrons. Compare with *antioxidants*.

oxidation The loss of one or more electrons (or hydrogen atoms) by an atom, ion, or molecule. Compare with *reduction*.

oxidative phosphorylation (fos"-for-ih-lay'-shun) The production of ATP using energy derived from the transfer of electrons in the electron transport system of mitochondria; occurs by chemiosmosis.

oxygen-carrying capacity The maximum amount of oxygen transported by hemoglobin.

oxygen debt The oxygen necessary to metabolize the lactic acid produced during strenuous exercise.

oxygen-hemoglobin dissociation curve A curve depicting the percentage saturation of hemoglobin with oxygen, as a function of certain variables such as oxygen concentration, carbon dioxide concentration, or pH.

oxyhemoglobin Hemoglobin that has combined with oxygen.

oxytocin (ok"-see-tow'-sin) Hormone secreted by the hypothalamus and released by the posterior lobe of the pituitary gland; stimulates contraction of the pregnant uterus and the ducts of mammary glands.

ozone (O₃) A blue gas with a distinctive odor that is a human-made pollutant near Earth's surface (in the troposphere) but a natural and essential component of the stratosphere.

P generation (parental generation) Members of two different true-breeding lines that are crossed to produce the F₁ generation.

P680 Chlorophyll *a* molecules that serve as the reaction center of photosystem II, transferring photoexcited electrons to a primary acceptor; named for their absorption peak at 680 nm.

P700 Chlorophyll *a* molecules that serve as the reaction center of photosystem I, transferring photoexcited electrons to a primary acceptor; named for their absorption peak at 700 nm.

pacemaker (of the heart) See *sinoatrial (SA) node*.

Pacinian corpuscle (pah-sin'-ee-an kor'-pus-el) A receptor located in the dermis of the skin that responds to pressure.

paedomorphosis Retention of juvenile or larval features in a sexually mature animal.

pair bond A stable relationship between animals of opposite sex that ensures cooperative behavior in mating and rearing the young.

paleoanthropology (pay"-lee-o-an-thro-pol'-uh-gee) The study of human evolution.

Paleogene period See *Cenozoic era*.

Paleozoic era That part of geologic time extending from roughly 541 million to 252 million years ago; divided into six periods: Cambrian (appearance of many new animal groups, the *Cambrian radiation* or *Cambrian explosion*); Ordovician (diversification of sea life); Silurian (appearance of jawed fishes, terrestrial plants, and air-breathing animals); Devonian (appearance of sharks and bony fishes); Carboniferous (great

swamp forests formed coal deposits); Permian (ended with the greatest mass extinction of all time).

palindromic Reading the same forward and backward; DNA sequences are palindromic when the base sequence of one strand reads the same as its complement when both are read in the 5' to 3' direction.

palisade mesophyll (mez'-oh-fil) The vertically stacked, columnar mesophyll cells near the upper epidermis in certain leaves. Compare with *spongy mesophyll*.

pancreas (pan'-kree-us) Large gland located in the vertebrate abdominal cavity. The pancreas produces pancreatic juice containing digestive enzymes; also serves as an endocrine gland, secreting the hormones insulin and glucagon.

parabasilids Anaerobic, flagellated excavates that often live in animals; examples include trichonymphs and trichomonads.

parabronchi (sing., *parabronchus*) Thin-walled ducts in the lungs of birds; gases are exchanged across their walls.

paracrine regulation A type of regulation in which a signal molecule (e.g., certain hormones) diffuses through interstitial fluid and acts on nearby target cells. Compare with *autocrine regulation*.

paraphyletic group A group of organisms made up of a common ancestor and some, but not all, of its descendants. Compare with *monophyletic group* and *polyphyletic group*.

parapodia (par'-uh-poh'-dee-ah) (sing., *parapodium*) Paired, thickly bristled paddlelike appendages extending laterally from each segment of polychaete worms.

parasite A heterotrophic organism that obtains nourishment from the living tissue of another organism (the host).

parasitism (par'-uh-si-tiz'-m) A symbiotic relationship in which one member (the parasite) benefits and the other (the host) is adversely affected. Compare with *commensalism* and *mutualism*.

parasympathetic system A system of the autonomic division of the nervous system; functions to conserve or restore energy. Compare with *sympathetic system*.

parathyroid glands Small, pea-sized glands closely adjacent to the thyroid gland; they secrete parathyroid hormone, which regulates calcium and phosphate metabolism.

parathyroid hormone (PTH) A hormone secreted by the parathyroid glands; regulates calcium and phosphate metabolism.

Parazoa Some biologists divide the animal kingdom into two major groups: the Parazoa, which includes the sponges, and Eumetazoa, which includes all other animals.

parenchyma (par-en'-kih-mah) Highly variable living plant cells that have thin primary walls; function in photosynthesis, the storage of nutrients, and/or secretion.

parental imprinting See *imprinting* (definition 1).

parental investment The contribution that each parent makes in producing and rearing offspring; increases the probability that their offspring will survive.

parietal lobes The region of the cerebrum between the frontal lobes and the occipital lobes; contains the general sensory association areas.

parsimony The principle based on the experience that the simplest explanation is most probably the correct one.

parthenogenesis (par'-theh-noh-jen'-eh-sis) The development of an unfertilized egg into an adult organism; common among honeybees, wasps, and certain other arthropods.

partial pressure (of a gas) The pressure exerted by a gas in a mixture, which is the same pressure it would exert if alone. For example, the partial pressure of atmospheric oxygen (P_{O_2}) is 160 mm Hg at sea level.

passive immunity Temporary immunity that depends on the presence of immunoglobulins produced by another organism. Compare with *active immunity*.

passive ion channel A channel in the plasma membrane that permits the passage of specific ions such as Na^+ , K^+ , or Cl^- .

patch clamp technique A method that allows researchers to study the ion channels of a tiny patch of membrane by tightly sealing a micropipette to the patch and measuring the flow of ions through the channels.

patchiness See *clumped dispersion*.

pathogen (path'-oh-gen) An organism, usually a microorganism, capable of producing disease.

pathogen-associated molecular patterns (PAMPs) Distinctive molecules on bacteria and other pathogens that are not found in animals; pattern recognition receptors bind them.

pattern formation See *morphogenesis*.

pattern recognition receptors Receptors on certain types of animal cells that bind pathogen-associated molecular patterns (PAMPs); binding activates innate immune responses.

pedigree A chart constructed to show an inheritance pattern within a family through multiple generations.

peduncle The stalk of a flower or inflorescence.

pellicle A flexible outer covering consisting of protein; characteristic of certain protists (e.g., ciliates and euglenoids).

penis The male sexual organ of copulation in reptiles, mammals, and a few birds.

pentose A sugar molecule containing five carbons.

people overpopulation A situation in which there are too many people in a given geographic area; results in pollution, environmental degradation, and resource depletion. Compare with *consumption overpopulation*.

PEP carboxylase Enzyme with an extremely high affinity for CO_2 ; responsible for initial fixation of CO_2 in C_4 plants and CAM plants.

pepsin (pep'-sin) An enzyme produced in the stomach that initiates digestion of protein.

pepsinogen The precursor of pepsin; secreted by chief cells in the gastric glands of the stomach.

peptide (pep'-tide) A compound consisting of a chain of amino acid groups linked by peptide bonds. A dipeptide consists of two amino acids, a polypeptide of many.

peptide bond A distinctive covalent carbon-to-nitrogen bond that links amino acids in peptides and proteins.

peptide hormones Water-soluble hormones composed of proteins, such as oxytocin and antidiuretic hormone (ADH).

peptidoglycan (pep'-tid-oh-gly'-kan) A modified protein or peptide having an attached carbohydrate; component of the bacterial cell wall.

peptidyl transferase The ribosomal enzyme (a ribozyme) that catalyzes the formation of a peptide bond.

perception Conscious awareness of our internal and external environments as a result of processing sensory input and comparing present sensory experience with memories of past experience.

perennial plant (purr-en'-ee-ul) A woody or herbaceous plant that grows year after year (i.e., lives more than two years). Compare with *annual plant* and *biennial plant*.

perfect flower A flower that has both stamens and carpels. Compare with *imperfect flower*.

pericentriolar material Fibrils surrounding the centrioles in the microtubule-organizing centers in cells of animals and other organisms having centrioles.

pericycle (pehr'-eh-sy'-kl) A layer of meristematic cells typically found between the endodermis and phloem in roots.

periderm (pehr'-ih-durm) The outer bark of woody stems and roots; composed of cork cells, cork cambium, and cork parenchyma, along with traces of primary tissues.

peritoneum (per'-ih-tow-nee'-um) Largest serous membrane in the body; lines the walls of the abdominal and pelvic cavities and covers the organs in the cavities.

period An interval of geologic time that is a subdivision of an era; each period is divided into epochs.

periodic table A chart of the elements arranged in order by atomic number.

peripheral membrane protein A protein associated with one of the surfaces of a biological membrane. Compare with *integral membrane protein*.

peripheral nervous system (PNS) In vertebrates, the nerves and receptors that lie outside the central nervous system. Compare with *central nervous system (CNS)*.

peristalsis (pehr'-ih-stal'-sis) Rhythmic waves of muscular contraction and relaxation in the walls of hollow tubular organs, such as the ureter or parts of the digestive tract, that serve to move the contents through the tube.

peritubular capillaries In the mammalian kidney, a capillary network that surrounds each renal tubule; receives blood from the efferent arterioles.

permafrost Permanently frozen subsoil characteristic of frigid areas such as the tundra.

Permian period See *Paleozoic era*.

peroxisomes (pehr-ox'-ih-sohmz) In eukaryotic cells, membrane-enclosed organelles containing enzymes that produce or degrade hydrogen peroxide.

persistence A characteristic of certain chemicals that are extremely stable and may take many years to be broken down into simpler forms by natural processes.

petal One of the parts of the flower attached inside the whorl of sepals; petals are usually colored.

petiole (pet'-ee-ohl) The part of a leaf that attaches to a stem.

Pfr See *phytochrome*.

pH The negative logarithm of the hydrogen ion concentration of a solution (expressed as moles per liter). Neutral pH is 7, values less than 7 are acidic, and those greater than 7 are basic.

phage See *bacteriophage*.

phagocytosis (fag'-oh-sy-toh'-sis) Literally, "cell eating"; a type of endocytosis by which certain cells engulf food particles, microorganisms, foreign matter, or other cells. Compare with *pinocytosis* and *receptor-mediated endocytosis*.

pharmacogenetics A field of gene-based medicine in which drugs are personalized to match a patient's genetic makeup.

pharyngeal slits (fair-in'-jel) Openings that lead from the pharyngeal cavity to the outside; evolved as part of a filter-feeding system in chordates and later became modified for other functions, including gill slits in many aquatic vertebrates.

pharynx (fair'-inks) Part of the digestive tract. In complex vertebrates, it is bounded anteriorly by the mouth and nasal cavities and posteriorly by the esophagus and larynx; the throat region in humans.

phenetics (feh-neh'-tik-s) An approach to classification based on measurable similarities in phenotypic characters without consideration of homology or other evolutionary relationships. Compare with *cladistics* and *evolutionary systematics*.

phenotype (fee'-noh-type) The physical or chemical expression of an organism's genes. Compare with *genotype*.

phenotype frequency The proportion of a particular phenotype in the population. Compare with *allele frequency* and *genotype frequency*.

phenylketonuria (PKU) (fee'-nl-kee'-toh-noor'-ee-ah) An inherited disease in which there is a deficiency of the enzyme that normally converts phenylalanine to tyrosine; results in intellectual disability if untreated.

pheromone (fer'-oh-mone) A substance secreted by an organism to the external environment that influences the development or behavior of other members of the same species.

phloem (flo'-em) The vascular tissue that conducts dissolved sugar and other organic compounds in plants.

phosphatases Enzymes that catalyze the removal of phosphate groups from proteins and other molecules. Compare with *kinases* and *protein kinases*.

phosphate group A weakly acidic functional group that can release one or two hydrogen ions.

phosphodiesterase Enzyme that breaks a phosphodiester bond; responsible for inactivating cyclic AMP by converting it to AMP.

phosphodiester linkage Covalent linkage between two nucleotides in a strand of DNA or RNA; includes a phosphate group bonded to the sugars of two adjacent nucleotides.

phosphoenolpyruvate (PEP) A 3-carbon phosphorylated compound that is an important intermediate in glycolysis and is a reactant in

the initial carbon fixation step in C₄ and CAM photosynthesis.

phosphoglycerate (PGA) Phosphorylated 3-carbon compound that is an important metabolic intermediate.

phospholipids (fos'-foh-lip'-idz) Lipids in which two fatty acids and a phosphorus-containing group are attached to glycerol; major components of cell membranes.

phosphorus cycle The worldwide circulation of phosphorus from the abiotic environment into living things and back into the abiotic environment.

phosphorylation (fos'-for-ih-lay'-shun) The introduction of a phosphate group into an organic molecule. See *kinases*.

photoautotroph An organism that obtains energy from light and synthesizes organic compounds from inorganic raw materials; includes plants, algae, and some bacteria. Compare with *photoheterotroph*, *chemoautotroph*, and *chemoheterotroph*.

photochemical smog Mixture of several air pollutants that injure plant tissues, irritate eyes, and cause respiratory problems in humans.

photoheterotroph An organism that can carry out photosynthesis to obtain energy but cannot fix carbon dioxide and therefore requires organic compounds as a carbon source; includes some bacteria and archaea. Compare with *photoautotroph*, *chemoautotroph*, and *chemoheterotroph*.

photolysis (foh-tol'-uh-sis) The photochemical splitting of water in the light-dependent reactions of photosynthesis; a specific enzyme is needed to catalyze this reaction.

photon (foh'-ton) A particle of electromagnetic radiation; one quantum of radiant energy.

photoperiodism (foh'-teh-peer'-ee-o-dizm) The physiological response (such as flowering) of plants to variations in the length of daylight and darkness.

photophosphorylation (foh'-toh-fos-for-ih-lay'-shun) The production of ATP in photosynthesis.

photoreceptor (foh'-toh-ree-sep'-tor) (1) A sense organ specialized to detect light. (2) A pigment that absorbs light before triggering a physiological response.

photorespiration (foh'-toh-res-pur-ay'-shun) The process that reduces the efficiency of photosynthesis in C₃ plants during hot spells in summer; consumes oxygen and produces carbon dioxide through the degradation of Calvin cycle intermediates.

photosynthesis The biological process that captures light energy and transforms it into the chemical energy of organic molecules (e.g., carbohydrates), which are manufactured from carbon dioxide and water.

photosystem One of two photosynthetic units responsible for capturing light energy and transferring excited electrons; photosystem I strongly absorbs light of about 700 nm, whereas photosystem II strongly absorbs light of about 680 nm. See *antenna complex* and *reaction center*.

phototaxis Movement of a cell or organism in response to light.

phototroph (foh'-toh-trof) Organism that uses light as a source of energy. Compare

with *chemotroph*. See *photoautotroph* and *photoheterotroph*.

phototropins (foh'-toh-troh'-pinz) Family of yellow pigments responsible for such blue light responses as the phototropic response and stomatal opening.

phototropism (foh'-toh-troh'-pizm) The growth of a plant in response to the direction of light.

phycocyanin (fy'-koh-sy-ah'-nin) A blue pigment found in cyanobacteria and red algae.

phycoerythrin (fy'-koh-ee-rih'-thrin) A red pigment found in cyanobacteria and red algae.

phyletic gradualism The idea that evolution occurs by a slow, steady accumulation of genetic changes over time; also called *gradualism*. Compare with *punctuated equilibrium*.

phylogenetic species concept An alternative to the biological species concept in which for a population to be declared a separate species, it must have undergone evolution long enough for statistically significant differences to emerge. Also called *evolutionary species concept*. Compare with *species*.

phylogenetic systematics See *cladistics*.

phylogenetic tree A branching diagram that shows lines of descent among a group of related species.

phylogeny (fy-loj'-en-ee) The complete evolutionary history of a group of organisms.

phylum (fy'-lum) (pl., *phyla*) A taxonomic grouping of related, similar classes; a category beneath the kingdom and above the class.

phytoalexins Antimicrobial compounds produced by plants that limit the spread of pathogens such as fungi.

phytochemicals Non-nutrient compounds found in plants that are biologically active in the body and may promote health.

phytochrome (fy'-toh-krome) A blue-green, proteinaceous pigment involved in a wide variety of physiological responses to light; occurs in two interconvertible forms, Pr (red-absorbing phytochrome) and Pfr (far-red-absorbing phytochrome).

phytoplankton (fy'-toh-plank'-tun) Microscopic floating algae and cyanobacteria that are the base of most aquatic food webs. Compare with *zooplankton*. See *plankton* and *nanoplankton*.

pia mater (pee'-a may'-ter) The inner membrane covering the brain and spinal cord; the innermost of the meninges; also see *dura mater* and *arachnoid*.

pigment A substance that selectively absorbs light of specific wavelengths.

pili (pie'-lie) (sing., *pilus*) Hairlike structures on the surface of many bacteria; function in conjugation or attachment. A sex pilus forms a cytoplasmic bridge with another bacterium and transfers DNA via this bridge.

pineal gland (pie-nee'-al) Endocrine gland located in the brain.

pinocytosis (pin'-oh-sy-toh'-sis) Cell drinking; a type of endocytosis by which cells engulf and absorb droplets of liquids. Compare with *phagocytosis* and *receptor-mediated endocytosis*.

pioneer The first organism to colonize an area and begin the first stage of succession.

pistil The female reproductive organ of a flower; consists of either a single carpel or two or more fused carpels. See *carpel*.

pith The innermost tissue in the stems and roots of many herbaceous plants; primarily a storage tissue.

pituitary gland (pi-too'-ih-tehr"-ee) An endocrine gland located below the hypothalamus; secretes several hormones that influence a wide range of physiological processes.

piwi-associated RNA (piRNA) Small RNAs (26–31 bases) involved in gene silencing of *retrotransposons* and regulating gene activity in animal germ line cells.

placenta (plah-sen'-tah) The partly fetal and partly maternal organ whereby materials are exchanged between fetus and mother in the uterus of placental mammals.

placoderms (plak'-oh-durmz) A group of extinct jawed fishes.

placoid scales (pla'-koid) The toothlike scales found in sharks and other cartilaginous fishes.

plankton Free-floating, mainly microscopic aquatic organisms found in the upper layers of the water; consisting of phytoplankton and zooplankton. Compare with *nekton*.

plants Members of the archaeplastid supergroup, distinguished by development of sporophytes from multicellular embryos enclosed in maternal tissues; also called *land plants*.

planula larva (plan'-yoo-lah) A ciliated larval form found in cnidarians.

plasma The fluid portion of blood in which red blood cells, white blood cells, and platelets are suspended.

plasma cell Cell that secretes antibodies; a differentiated B lymphocyte (B cell).

plasma membrane The selectively permeable surface membrane that encloses the cell contents and through which all materials entering or leaving the cell must pass.

plasma proteins Proteins such as albumins, globulins, and fibrinogen that circulate in the blood plasma.

plasmid (plaz'-mid) Small, circular, double-stranded DNA molecule that carries genes separate from those in the main DNA of a cell.

plasmodesmata (sing., *plasmodesma*) Cytoplasmic channels connecting adjacent plant cells and allowing for the movement of molecules and ions between cells.

plasmodial slime mold (plaz-moh'-dee-uhl) A funguslike amoebozoan protist whose feeding stage consists of a plasmodium; compare with *cellular slime mold*.

plasmodium (plaz-moh'-dee-um) A multinucleate mass of living matter that moves and feeds in an amoeboid fashion.

plasmogamy (1) Fusion of the cytoplasm of two cells without fusion of nuclei. (2) A stage in the asexual reproduction of some fungi; hyphae of two compatible mating types come together, and their cytoplasm fuses.

plasmolysis (plaz-mol'-ih-sis) The shrinkage of cytoplasm and the pulling away of the plasma membrane from the cell wall when a plant cell (or other walled cell) loses water, usually in a hypertonic environment.

plastids (plas'-tidz) A family of membrane-enclosed organelles occurring in photosynthetic eukaryotic cells; include chloroplasts, chromoplasts, and amyloplasts and other leukoplasts.

platelets (playt'-lets) Cell fragments in vertebrate blood that function in clotting; also called *thrombocytes*.

platyhelminths The phylum of acoelomate animals commonly known as *flatworms*.

pleiotropy The ability of a single gene to have multiple effects.

pleural membrane (ploor'-ul) The membrane that lines the thoracic cavity and envelops each lung.

ploidy The number of chromosome sets in a nucleus or cell. See *haploid*, *diploid*, and *polyploid*.

plumule (ploom'-yool) The embryonic shoot apex, or terminal bud, located above the point of attachment of the cotyledon(s).

pluripotent (ploor-i-poh'-tent) A term describing a stem cell that can divide to give rise to many, but not all, types of cells in an organism. Compare with *totipotent*.

pneumatophore (noo-mat'-uh-for") Roots that extend up out of the water in swampy areas and are thought to provide aeration between the atmosphere and submerged roots.

polar body A small *n* cell produced during oogenesis in female animals that does not develop into a functional ovum.

polar covalent bond Chemical bond formed by the sharing of electrons between atoms that differ in electronegativity; the end of the bond near the more electronegative atom has a partial negative charge, and the other end has a partial positive charge. Compare with *nonpolar covalent bond*.

polar molecule Molecule that has one end with a partial positive charge and the other with a partial negative charge; polar molecules are generally soluble in water. Compare with *nonpolar molecule*.

polar nucleus In flowering plants, one of two *n* nuclei in the embryo sac that fuse with a sperm during double fertilization to form the *3n* endosperm.

pollen grain The immature male gametophyte of seed plants (gymnosperms and angiosperms) that produces sperm capable of fertilization.

pollen tube In gymnosperms and flowering plants, a tube or extension that forms after germination of the pollen grain and through which male gametes (sperm cells) pass into the ovule.

pollination (pol'-uh-nay'-shen) In seed plants, the transfer of pollen from the male to the female part of the plant.

polyadenylation (pol'-ee-a-den-uh-lay'-shun) That part of eukaryotic mRNA processing in which multiple adenine-containing nucleotides (a poly-A tail) are added to the 3' end of the molecule.

polyandry A mating system in which a female mates with several males during a breeding season. Compare with *polygyny*.

poly-A tail See *polyadenylation*.

polydnaviruses Virus particles that consist of multiple circles of dsDNA surrounded by capsid proteins and an envelope; they lack DNA coding for proteins needed for viral replication, but this DNA is provided by ovary cells of the wasps they inhabit.

polygenic inheritance (pol'-ee-jen'-ik) Inheritance in which several independently assorting or loosely linked nonallelic genes modify the intensity of a trait or contribute to the phenotype in additive fashion.

polygyny A mating system in which a male animal mates with many females during a breeding season. Compare with *polyandry*.

polymer (pol'-ih-mer) A molecule built up from repeating subunits of the same general type (monomers); examples include proteins, nucleic acids, or polysaccharides.

polymerase chain reaction (PCR) A method by which a targeted DNA fragment is amplified in vitro to produce millions of copies.

polymorphism (pol'-ee-mor'-fizm) (1) The existence of two or more phenotypically different individuals within a population. (2) The presence of detectable variation in the genomes of different individuals in a population.

polynucleotide A DNA or RNA polymer consisting of a chain of many nucleotides.

polyp (pol'-ip) A hydralike animal; the sessile stage of the life cycle of certain cnidarians. Compare with *medusa*.

polypeptide See *peptide*.

polyphyletic group (pol'-ee-fye-let'-ik) A group made up of organisms that evolved from two or more different ancestors. Compare with *monophyletic group* and *paraphyletic group*.

polyploid (pol'-ee-ploid) The condition of having more than two sets of chromosomes per nucleus. Compare with *diploid* and *haploid*.

polysome A complex consisting of a number of ribosomes attached to an mRNA during translation; also known as a *polysome*.

polysaccharide (pol-ee-sak'-ah-ride) A carbohydrate consisting of many monosaccharide subunits (e.g., starch, glycogen, and cellulose).

polysome See *polysome*.

polyspermy The fertilization of an egg by more than one sperm.

polytene A term describing a giant chromosome consisting of many parallel DNA double helices. Polytene chromosomes are typically found in cells of the salivary glands and some other tissues of certain insects, such as the fruit fly, *Drosophila*.

polyunsaturated fatty acid See *fatty acid*.

pons (ponz) The white bulge that is the part of the brain stem between the medulla and the midbrain; connects various parts of the brain.

population A group of organisms of the same species that live in a defined geographic area at the same time.

population bottleneck See *bottleneck*.

population crash An abrupt decline in the size of a population.

population density The number of individuals of a species per unit of area or volume at a given time.

population dynamics The study of changes in populations, such as how and why population numbers change over time.

population ecology That branch of biology that deals with the numbers of a particular species that are found in an area and how and why those numbers change (or remain fixed) over time.

population genetics The study of genetic variability in a population and of the forces that act on it.

population growth momentum The continued growth of a population after fertility rates have declined, as a result of a population's young age structure.

positional information The exposure of cells to different concentrations of signaling molecules that specify where the cell is located relative to the body's axes; this information affects cell differentiation and tissue formation.

positive control A genetic control system in which a regulatory protein binds to DNA, turning on transcription of a gene. Compare with *negative control*.

positive feedback system A system in which a change in some steady state triggers a response that intensifies the changing condition. Compare with *negative feedback system*.

posterior Toward the tail end of a bilaterally symmetrical animal. Compare with *anterior*.

posterior pituitary The posterior, neuroendocrine lobe of the pituitary gland; secretes oxytocin and antidiuretic hormone (ADH). Compare with *anterior pituitary*.

postsynaptic neuron A neuron that transmits an impulse away from a synapse. Compare with *presynaptic neuron*.

posttranslational control Regulation of gene expression that controls activity or functions of proteins, usually by phosphorylation or other chemical modifications of the protein. Compare with *transcriptional-level control*, *translational-level control*, and *posttranscriptional control*.

posttranscriptional control Regulation of gene expression that occurs after the transcription of an mRNA, usually referring to pre-mRNA processing, mRNA export, or mRNA stability. Compare with *transcriptional-level control*, *translational-level control*, and *posttranslational control*.

postzygotic barrier One of several reproductive isolating mechanisms that prevent gene flow between species after fertilization has taken place (e.g., *hybrid inviability*, *hybrid sterility*, and *hybrid breakdown*). Compare with *prezygotic barrier*.

potential energy Stored energy; energy that can do work as a consequence of its position or state. Compare with *kinetic energy*.

potentiation A form of synaptic enhancement (increase in neurotransmitter release) that can last for several minutes; occurs when a presynaptic neuron continues to transmit action potentials at a high rate for a minute or longer.

Pr See *phytochrome*.

preadaptation A novel evolutionary change in a pre-existing biological structure that enables it to have a different function; feathers, which evolved from reptilian scales, represent a preadaptation for flight.

prebiotic soup hypothesis The hypothesis that simple organic molecules that are the precursors of life originated and accumulated at Earth's surface, in shallow seas or on rock or clay surfaces. Compare with *iron-sulfur world hypothesis*.

predation Relationship in which one organism (the predator, a secondary or higher level consumer) devours another organism (the prey).

predator See *predation*.

prefrontal cortex Region of the frontal lobes anterior to the motor areas; important in intellect, memory, judgment, language, emotion; and in interpreting incoming sensory information.

prehensile tail Tail adapted for grasping.

preimplantation genetic diagnosis (PGD) Technique by which single cells of embryos conceived by in vitro fertilization are tested for certain genetic diseases prior to the implantation of the embryo in the uterus.

premolars In mammals, teeth positioned between the canines and molars; adapted for crushing and grinding; compare with *incisors*, *canines*, and *molars*.

pre-mRNA RNA precursor to mRNA in eukaryotes; contains both introns and exons.

prenatal Pertaining to the time before birth.

preprophase band In plant cells, a dense array of microtubules just inside of the plasma membrane that appears just prior to mitosis and determines the plane in which the cell will divide.

pressure-flow model The mechanism by which dissolved sugar is thought to be transported in phloem; caused by a pressure gradient between the source (where sugar is loaded into the phloem) and the sink (where sugar is removed from phloem).

presynaptic neuron A neuron that transmits an impulse to a synapse. Compare with *postsynaptic neuron*.

prezygotic barrier One of several reproductive isolating mechanisms that interfere with fertilization between male and female gametes of different species (e.g., *temporal isolation*, *habitat isolation*, *behavioral isolation*, *mechanical isolation*, and *gametic isolation*). Compare with *postzygotic barrier*.

primary cilium Single nonmotile cilium on the cell surface of animal cells, especially those of vertebrates; binds specific molecules and serves as a "cellular antenna" in many signaling pathways.

primary consumer An animal that eats producers (e.g., plants or algae).

primary growth An increase in the length of a plant that occurs at the tips of the shoots and roots due to the activity of apical meristems. Compare with *secondary growth*.

primary immune response The response of the immune system to first exposure to an antigen. Compare with *secondary immune response*.

primary mycelium A mycelium in which the cells are monokaryotic and haploid; a mycelium that grows from either an ascospore or a basidiospore. Compare with *secondary mycelium*.

primary oocytes Diploid cells that develop from oogonia; undergo a first meiotic division, giving rise to haploid secondary oocytes.

primary producer See *autotroph*.

primary productivity The amount of light energy converted to organic compounds by autotrophs in an ecosystem over a given period. Compare with *secondary productivity*. See *gross primary productivity (GPP)* and *net primary productivity (NPP)*.

primary spermatocytes Diploid cells that develop from spermatogonia; undergo a first meiotic division, giving rise to haploid secondary spermatocytes.

primary structure (of a protein) The complete sequence of amino acids in a polypeptide chain, beginning at the amino end and ending at the carboxyl end. Compare with *secondary*, *tertiary*, and *quaternary protein structure*.

primary succession An ecological succession that occurs on land that has not previously been inhabited by plants; no soil is present initially. See *succession*. Compare with *secondary succession*.

primates Mammals that share such traits as flexible hands and feet with five digits; a strong social organization; and front-facing eyes; includes lemurs, tarsiers, monkeys, apes, and humans.

primer See *RNA primer*.

primitive groove See *primitive streak*.

primitive streak Dynamic, constantly changing structure that forms at the midline of the blastodisc in birds, mammals, and some other vertebrates. It is active in gastrulation as cells migrate to a narrow furrow at its center, the primitive groove, and sink into the interior of the embryo. The anterior end of the primitive streak is Hensen's node.

primosome A complex of proteins responsible for synthesizing the RNA primers required in DNA synthesis.

principle In science, a statement of a rule that explains how something works. A scientific principle has withstood repeated testing.

prion (pri'-on) An infectious agent that consists only of protein.

producer See *autotroph*.

product Substance formed by a chemical reaction. Compare with *reactant*.

product rule The rule for combining the probabilities of independent events by multiplying their individual probabilities. Compare with *sum rule*.

profundal zone (pro-fun'-dl) The deepest zone of a large lake, located below the level of penetration by sunlight. Compare with *littoral zone* and *limnetic zone*.

progesterone (pro-jes'-ter-own) A steroid hormone secreted by the ovary (mainly by the corpus luteum) and placenta; stimulates the uterus (to prepare the endometrium for implantation) and breasts (for milk secretion).

progymnosperm (pro-jim'-noh-sperm) An extinct group of plants that may have been the ancestors of gymnosperms.

prokaryote (pro-kar'-ee-ote) A cell that lacks a nucleus and other membrane-enclosed organelles; includes the bacteria and archaea (domains Bacteria and Archaea). Compare with *eukaryote*.

prokaryotic cell See *prokaryote*.

prolactin Hormone secreted by the pituitary gland that stimulates cells of the mammary glands to produce milk in a nursing mother. Helps maintain water and electrolyte balance in fishes and amphibians. Inhibits metamorphosis in amphibians and stimulates molting in reptiles. Has a role in immune function and in the formation of new blood vessels.

prometaphase Stage of mitosis during which spindle microtubules attach to kinetochores of chromosomes, which begin to move toward the cell's midplane; occurs after prophase and before metaphase.

promoter The nucleotide sequence in DNA to which RNA polymerase attaches to begin transcription.

prop root An adventitious root that arises from the stem and provides additional support for a plant such as corn.

prophage (pro'-faj) Bacteriophage nucleic acid inserted into the bacterial DNA.

prophase The first stage of mitosis. During prophase the chromosomes become visible as distinct structures, the nuclear envelope breaks down, and a spindle forms.

prophase I See *meiosis* and *meiosis I*.

prophase II See *meiosis* and *meiosis II*.

proplastids Organelles that are plastid precursors; may mature into various specialized plastids, including chloroplasts, chromoplasts, or leukoplasts.

proprioceptors (pro"-pree-oh-sep'-torz) Receptors in muscles, tendons, and joints that respond to changes in movement, tension, and position; enable an animal to perceive the position of its body.

prostaglandins (pros"-tah-glan'-dinz) A group of local regulators derived from fatty acids; synthesized by most cells of the body and produce a wide variety of effects; sometimes called *local hormones*.

prostate gland A gland in male animals that produces an alkaline secretion that is part of the semen.

protease An enzyme that breaks down proteins by cleaving peptide bonds.

proteasome A large multiprotein structure that recognizes and degrades protein molecules tagged with ubiquitin into short, nonfunctional peptide fragments.

protein A large, complex organic compound composed of covalently linked amino acid subunits; contains carbon, hydrogen, oxygen, nitrogen, and sulfur.

protein domain See *domain* (definition 1).

protein kinases Enzymes that activate or inactivate other proteins by phosphorylating (adding phosphate groups to) them.

proteomics The study of all the proteins expressed by a cell at a given time.

Proterozoic eon The period of Earth's history that began approximately 2.5 billion years ago and ended 541 million years ago; marked by the accumulation of oxygen and the appearance of the first multicellular eukaryotic life-forms.

prothallus (pro-thal'-us) (pl., *prothalli*) The free-living, *n* gametophyte in ferns and other seedless vascular plants.

protists (pro'-tists) Eukaryotic organisms that may be unicellular, colonial, or simple multicellular; for example, algae, amoebas, ciliates, and slime molds.

protobionts (pro"-toh-by'-ontz) Assemblages of organic polymers that spontaneously form under certain conditions. Protobionts may have been involved in chemical evolution.

proton A particle present in the nuclei of all atoms that has one unit of positive charge and a mass of 1 atomic mass unit (amu). Compare with *electron* and *neutron*.

protonema (pro"-toh-nee'-mah) (pl., *protonemata*) In mosses, a filament of *n* cells that

grows from a spore and develops into leafy moss gametophytes.

protonephridia (pro"-toh-nef-rid'-ee-ah) (sing., *protonephridium*) The flame-cell excretory organs of flatworms and some other simple invertebrates.

proto-oncogene A gene that normally promotes cell division in response to the presence of certain growth factors; when mutated, it may become an oncogene, possibly leading to the formation of a cancer cell. Compare with *oncogene*.

protostomes (pro'-toh-stomes) Animals that belong to the Protostomia, one of the major animal clades. Include the annelids, arthropods, and mollusks. Compare with *deuterostomes*.

protozoa (proh"-toh-zoh'-a) (sing., *protozoon*) An informal group of unicellular, animal-like protists, including amoebas, foraminiferans, actinopods, ciliates, flagellates, and apicomplexans. (The adjectival form is *protozoan*.)

provirus (pro-vy'-rus) A part of a virus, consisting of nucleic acid only, that was inserted into a host genome. See *DNA provirus*.

proximal Closer to the point of reference. Compare with *distal*.

proximal convoluted tubule The part of the renal tubule that extends from Bowman's capsule to the loop of Henle. Compare with *distal convoluted tubule*.

proximate causes (of behavior) The immediate causes of behavior, such as genetic, developmental, and physiological processes that permit the animal to carry out a specific behavior. Compare with *ultimate causes (of behavior)*.

pseudocoelom (sue"-doh-see'-lom) A body cavity between the mesoderm and endoderm; derived from the blastocoel. Compare with *coelom*.

pseudocoelomate (sue"-doh-seel'-oh-mate) An animal having a pseudocoelom. Compare with *coelomate* and *acoelomate*.

pseudoplasmodium (sue"-doh-plaz-moh'-dee-um) In cellular slime molds, an aggregation of amoeboid cells that forms a spore-producing fruiting body during reproduction.

pseudopodium (sue"-doh-poe'-dee-um) (pl., *pseudopodia*) A temporary extension of an amoeboid cell that is used for feeding and locomotion.

pterosaurs (ter'-uh-sawrs) Flying reptiles of the Mesozoic era.

puberty The period of sexual maturation during which secondary sex characteristics begin to develop and the individual becomes capable of reproducing.

puff In a polytene chromosome, a decondensed region that is a site of intense RNA synthesis.

pulmonary circulation The part of the circulatory system that delivers blood to and from the lungs for oxygenation. Compare with *systemic circulation*.

pulse, arterial The alternate expansion and recoil of an artery.

punctuated equilibrium The idea that evolution proceeds with periods of little or no genetic change, followed by very active phases, so that major adaptations or clusters of adaptations appear suddenly in the fossil record. Compare with *phyletic gradualism*.

Punnett square The grid structure, first developed by Reginald Punnett, that allows direct calculation of the probabilities of occurrence of all possible offspring of a genetic cross.

pupa (pew'-pah) (pl., *pupae*) A stage in the development of an insect, between the larva and the imago (adult); a form that neither moves nor feeds and may be in a cocoon.

purines (pure'-eenz) Nitrogenous bases with carbon and nitrogen atoms in two attached rings (e.g., adenine and guanine); components of nucleic acids, ATP, GTP, NAD⁺, and certain other biologically active substances. Compare with *pyrimidines*.

pyramid of biomass Ecological pyramid that illustrates the total biomass, as, for example, the total dry weight, of all organisms at each trophic level in an ecosystem. Compare with *pyramid of energy* and *pyramid of numbers*.

pyramid of energy Ecological pyramid that shows the energy flow through each trophic level of an ecosystem. Compare with *pyramid of biomass* and *pyramid of numbers*.

pyramid of numbers Ecological pyramid that shows the number of organisms at each trophic level in a given ecosystem. Compare with *pyramid of biomass* and *pyramid of energy*.

pyrimidines (pyr-im'-ih-deenz) Nitrogenous bases, each composed of a single ring of carbon and nitrogen atoms (e.g., thymine, cytosine, and uracil); components of nucleic acids. Compare with *purines*.

pyruvate (pyruvic acid) A 3-carbon compound; the end product of glycolysis.

qPCR *Quantitative PCR*, a method for measuring levels of mRNA in cells; total cellular mRNA is reverse transcribed as cDNA, which is then amplified by PCR. The cellular abundance of a particular mRNA can be calculated by measuring the amount of DNA complementary to it produced during each amplification cycle. Also called *rtPCR* or *real time PCR*.

quadrupedal (kwad'-roo-ped"-ul) Walking on all fours. Compare with *bipedal*.

quantitative PCR See *qPCR*.

quantitative trait A trait that shows continuous variation in a population (e.g., human height) and typically has a polygenic inheritance pattern.

Quaternary period See *Cenozoic era*.

quaternary structure (of a protein) The overall conformation of a protein produced by the interaction of two or more polypeptide chains. Compare with *primary*, *secondary*, and *tertiary protein structure*.

r selection A reproductive strategy recognized by some ecologists, in which a species typically has a small body size, rapid development, and short lifespan and devotes a large proportion of its metabolic energy to the production of offspring. Compare with *K selection*.

r strategist See *r selection*.

radial cleavage The pattern of blastomere production in which the cells are located directly above or below one another; characteristic of early deuterostome embryos. Compare with *spiral cleavage*.

radial symmetry A body plan in which any section through the mouth and down the length of the body divides the body into similar halves. Jellyfish and other cnidarians have radial symmetry. Compare with *bilateral symmetry*.

radicle (rad'-ih-kl) The embryonic root of a seed plant.

radioactive decay The process in which a radioactive element emits radiation, and as a result, its nucleus changes into the nucleus of a different element.

radioisotopes Unstable isotopes that spontaneously emit radiation; also called *radioactive isotopes*.

radiolarians Those actinopods that secrete elaborate shells of silica (glass).

radula (rad'-yoo-lah) A rasplike structure in the digestive tract of chitons, snails, squids, and certain other mollusks.

rain shadow An area that has very little precipitation, found on the downwind side of a mountain range. Deserts often occur in rain shadows.

random dispersion The spatial distribution pattern of a population in which the presence of one individual has no effect on the distribution of other individuals. Compare with *clumped dispersion* and *uniform dispersion*.

range The area where a particular species occurs. Compare with *home range*.

Ras proteins A group of small G proteins, named by their discovery in *rat* sarcoma cancer cells; important in many signaling pathways.

ratite (rat'-it) A flightless bird, such as an ostrich or kiwi.

ray A chain of parenchyma cells (one to many cells thick) that functions for lateral transport in stems and roots of woody plants.

ray-finned fishes A class (Actinopterygii) of modern bony fishes; contains about 95% of living fish species.

reabsorption The selective removal of certain substances from the glomerular filtrate by the renal tubules and collecting ducts of the kidney, and their return into the blood.

reactant Substance that participates in a chemical reaction. Compare with *product*.

reaction center The portion of a photosystem that includes chlorophyll *a* molecules capable of transferring electrons to a primary electron acceptor, which is the first of several electron acceptors in a series. See *antenna complex* and *photosystem*.

realized niche The lifestyle that an organism actually pursues, including the resources that it actually uses. An organism's realized niche is narrower than its fundamental niche because of interspecific competition. Compare with *fundamental niche*.

real time PCR (rtPCR) See *qPCR*.

Recent Africa Origin model (RAO) See (*recent*) *out-of-Africa model*.

(recent) out-of-Africa model (also called *Recent Africa Origin* or *RAO*) Hypothesis that modern humans (*Homo sapiens*) originated in Africa and subsequently migrated to other parts of the world.

receptacle The end of a flower stalk where the flower parts (sepals, petals, stamens, and carpels) are attached.

reception Process of detecting a stimulus.

receptor (1) In cell biology, a molecule on the surface of a cell, or inside a cell, that serves

as a recognition or binding site for signaling molecules such as hormones, antibodies, or neurotransmitters. (2) A sensory receptor. See *sensory receptor*.

receptor down-regulation The process by which some hormone receptors decrease in number, thereby suppressing the sensitivity of target cells to a hormone. Compare with *receptor up-regulation*.

receptor-mediated endocytosis A type of endocytosis in which extracellular molecules become bound to specific receptors on the cell surface and then enter the cytoplasm enclosed in vesicles. Compare with *phagocytosis* and *pinocytosis*.

receptor potential The change in membrane potential by a sensory receptor in response to a stimulus.

receptor up-regulation The process by which some hormone receptors increase in number, thereby increasing the sensitivity of the target cells to a hormone. Compare with *receptor down-regulation*.

recessive allele (al-leel') An allele that is not expressed in the heterozygous state. Compare with *dominant allele*.

reciprocal altruism A type of altruistic behavior in which an animal helps nonrelatives if they are likely to repay the debt in the future.

recombinant DNA Any DNA molecule made by combining genes from different organisms.

recombination, genetic The appearance of new allele combinations. Recombination in eukaryotes generally results from meiotic events, either crossing-over or shuffling of chromosomes.

rectum The last region of the large intestine.

red alga A member of a diverse group of archaeplastid algae that contain the pigments chlorophyll *a*, carotenoids, phycocyanin, and phycoerythrin.

red blood cell (RBC) See *erythrocyte*.

redox reaction (ree'-doh) The chemical reaction in which one or more electrons are transferred from one substance (the substance that becomes oxidized) to another (the substance that becomes reduced). See *oxidation* and *reduction*.

red tide A red or brown coloration of ocean water caused by a population explosion, or bloom, of dinoflagellates.

reduction The gain of one or more electrons (or hydrogen atoms) by an atom, ion, or molecule. Compare with *oxidation*.

reductionism Learning about a structure or process by studying its simplest components.

re-emerging diseases Diseases that have been almost eradicated and then suddenly recur, causing an epidemic. Compare with *emerging diseases*.

reflex action An automatic, involuntary response to a given stimulus that generally functions to restore homeostasis.

refractory period The brief period that elapses after the response of a neuron or muscle fiber, during which it cannot respond to another stimulus.

regulative development The very plastic developmental pattern in which each individual cell of an early embryo retains totipotency. Compare with *mosaic development*.

regulatory gene Gene that turns the transcription of other genes on or off.

regulatory T cells (T_{regs}) A population of T cells that help regulate immune responses.

reinforcement The increase in reproductive isolation that often occurs over time in a hybrid zone because natural selection strengthens and increases the number of prezygotic barriers between the two species.

releasing hormone A hormone secreted by the hypothalamus that stimulates secretion of a specific hormone by the anterior lobe of the pituitary gland.

renal (ree'-nl) Pertaining to the kidney.

renal artery An artery that branches from the aorta and delivers blood to the kidneys.

renal cortex The outer region of the mammalian kidney; surrounds the renal medulla. Compare with *renal medulla*.

renal medulla The inner region of the mammalian kidney. Compare with *renal cortex*.

renal pelvis The funnel-shaped chamber of the kidney that receives urine from the collecting ducts; urine then moves into one of the two ureters.

renin (reh'-nin) An enzyme released by the kidney in response to a decrease in blood pressure; activates a pathway leading to production of angiotensin II, a hormone that increases aldosterone release; aldosterone increases blood pressure.

replacement-level fertility The number of children a couple must produce to "replace" themselves. The average number is greater than two, because some children die before reaching reproductive age.

replication See *DNA replication*.

replication fork Y-shaped structure produced during the semiconservative replication of DNA.

repolarization The process of returning membrane potential to its resting level.

repressible operon An operon that is normally active, but can be controlled by a repressor protein, which becomes active when it binds to a corepressor; the active repressor binds to the operator, making the operon transcriptionally inactive. Compare with *inducible operon*.

repressor protein A negative regulatory protein that inhibits transcription when bound to DNA; some repressors require a corepressor to be active; some other repressors become inactive when bound to an inducer molecule. Compare with *activator protein*.

reproduction The process by which new individuals are produced. See *asexual reproduction* and *sexual reproduction*.

reproductive isolating mechanisms The reproductive barriers that prevent a species from interbreeding with another species; as a result, each species' gene pool is isolated from those of other species. See *prezygotic barrier* and *postzygotic barrier*.

reptiles Vertebrates characterized by dry skin with horny scales and adaptations for terrestrial reproduction; include turtles, snakes, and alligators; reptiles are a paraphyletic group unless birds are included.

residual volume The volume of air that remains in the lungs at the end of a normal exhalation.

resin A viscous organic material that certain plants produce and secrete into specialized ducts; may play a role in deterring disease organisms or plant-eating insects.

resolution See *resolving power*.

resolving power The ability of a microscope to show fine detail, defined as the minimum distance between two points at which they are seen as separate images; also called *resolution*.

resource partitioning The reduction of competition for environmental resources such as food that occurs among coexisting species as a result of each species' niche differing from the others in one or more ways.

respiration (1) Cellular respiration is the process by which cells generate ATP through a series of redox reactions. In aerobic cellular respiration, the terminal electron acceptor is molecular oxygen; in anaerobic cellular respiration, the terminal acceptor is an inorganic molecule other than oxygen. (2) Organismic respiration is the process of gas exchange between a complex animal and its environment, generally through a specialized respiratory surface, such as a lung or gill.

respiratory centers Centers in the medulla and pons that regulate breathing.

respiratory system The body system that carries on gas exchange; in vertebrates, consists of the lungs and airways.

response The action of effectors in response to a stimulus.

resting potential The membrane potential (difference in electric charge between the two sides of the plasma membrane) of a neuron in which no action potential is occurring. The typical resting potential is about -70 millivolts. Compare with *action potential*.

restoration ecology The scientific field that uses the principles of ecology to help return a degraded environment as closely as possible to its former undisturbed state.

restriction enzyme One of a class of enzymes that cleave DNA at specific base sequences; produced by bacteria to degrade foreign DNA; used in recombinant DNA technology.

restriction fragment length polymorphism (RFLP) A difference, or variation, in the genomic DNA of a population caused by the presence or absence of a restriction enzyme site.

restriction map A physical map of DNA in which sites cut by specific restriction enzymes serve as landmarks.

reticular activating system (RAS) (reh-tik'-yoo-lur) A diffuse network of neurons in the brain stem; responsible for maintaining consciousness.

retina (ret'-ih-nah) The innermost of the three layers (retina, choroid layer, and sclera) of the eyeball, which is continuous with the optic nerve and contains the light-sensitive rod and cone cells.

retinal Visual pigment derived from vitamin A; present in eyes of insects, mollusks, and vertebrates.

reticular cells See *ommatidium*.

retrotransposon A chromosomal DNA segment that can move to a different site within the genome by forming an RNA intermediate that is converted to a DNA fragment using reverse transcriptase; also called a *mobile genetic element*.

retrovirus (ret'-roh-vy'-rus) An RNA virus that uses reverse transcriptase to produce a DNA intermediate, known as a *DNA provirus*, in the host cell. See *DNA provirus*.

reverse transcriptase An enzyme produced by retroviruses that catalyzes the production of DNA using RNA as a template.

reverse transcriptase PCR A method for making DNA copies that are free of introns; mRNA is copied by reverse transcriptase, forming cDNA, which is then amplified by PCR. Also called *RT-PCR*.

reversible inhibitor A substance that forms weak bonds with an enzyme, temporarily interfering with its function; a reversible inhibitor is either competitive or noncompetitive. Compare with *irreversible inhibitor*.

Rh factors Red blood cell antigens, known as *D antigens*, first identified in *Rhesus* monkeys. People who have these antigens are Rh⁺; people lacking them are Rh⁻. See *erythroblastosis fetalis*.

rhizarians A diverse supergroup of amoeboid cells that often have hard outer shells, called tests, through which cytoplasmic projections extend; include forams, actinopods, and certain shell-less amoebas.

rhizobia See *nodules*.

rhizome (ry'-zome) A horizontal underground stem that bears leaves and buds and often serves as a storage organ and a means of asexual reproduction (e.g., iris).

rhodopsin (rho-dop'-sin) Visual purple; a light-sensitive pigment found in the rod cells of the vertebrate eye; a similar molecule is employed by certain bacteria in the capture of light energy to make ATP.

ribonucleic acid (RNA) A family of single-stranded nucleic acids that function mainly in protein synthesis

ribonucleoproteins Macromolecular complexes consisting of at least one polypeptide chain and one RNA molecule.

ribose The 5-carbon sugar present in RNA and in important nucleoside triphosphates such as ATP.

ribosomal RNA (rRNA) See *ribosomes*.

ribosomes (ry'-boh-sohmz) Organelles that are part of the protein synthesis machinery of both prokaryotic and eukaryotic cells; consist of a larger and smaller subunit, each composed of ribosomal RNA (rRNA) and ribosomal proteins.

ribozyme (ry'-boh-zime) A molecule of RNA that has catalytic properties.

ribulose biphosphate (RuBP) A 5-carbon phosphorylated compound with a high energy potential that reacts with carbon dioxide in the initial step of the Calvin cycle.

ribulose biphosphate carboxylase/oxygenase See *rubisco*.

RNA interference (RNAi) Phenomenon in which certain small RNA molecules interfere with the expression of genes or their RNA transcripts; RNA interference involves small interfering RNAs (siRNAs), microRNAs (miRNAs), piwi-associated RNAs (piRNAs), and other kinds of short RNA molecules.

RNA polymerase An enzyme that catalyzes the synthesis of RNA from a DNA template.

RNA primer The sequence of about five RNA nucleotides that are synthesized during DNA

replication to provide a 3' end to which DNA polymerase adds nucleotides. The RNA primer is later degraded and replaced with DNA.

RNA-seq analysis A method for measuring levels of mRNAs in cells; total cellular RNA is reverse transcribed to form cDNA fragments, which are then subjected to high-speed DNA sequencing.

RNA world A model that proposes that during the evolution of cells, RNA was the first informational molecule to evolve, followed at a later time by proteins and DNA.

rod One of the rod-shaped, light-sensitive cells of the retina that are particularly sensitive to dim light and mediate black-and-white vision. Compare with *cone*.

root cap A covering of cells over the root tip that protects the delicate meristematic tissue directly behind it.

root graft The process of roots from two different plants growing together and becoming permanently attached to each other.

root hair An extension, or outgrowth, of a root epidermal cell. Root hairs increase the absorptive capacity of roots.

root pressure The pressure in xylem sap that occurs as a result of the active absorption of mineral ions followed by the osmotic uptake of water into roots from the soil.

root system The underground portion of a plant that anchors it in the soil and absorbs water and dissolved minerals. Compare with *shoot system*.

rough ER See *endoplasmic reticulum*.

r-selected species See *r selection*.

RT-PCR See *reverse transcriptase PCR*.

rtPCR (real time PCR) See *qPCR*.

rubisco The common name of ribulose biphosphate carboxylase/oxygenase, the enzyme that catalyzes the fixation of carbon dioxide in the Calvin cycle.

rugae (roo'-jee) Folds, such as those in the lining of the stomach.

runner See *stolon*.

runoff Movement of excess surface water over land toward bodies of water.

S phase Stage in interphase of the cell cycle during which DNA and other chromosomal constituents are synthesized. Compare with *G₁ phase* and *G₂ phase*.

sacculle The structure within the vestibule of the inner vertebrate ear that along with the utricle houses the receptors of static equilibrium.

salicylic acid A signaling molecule that helps plants defend against insect pests and pathogens such as viruses by helping activate systemic acquired resistance.

salinity The concentration of dissolved salts (e.g., sodium chloride) in a body of water.

salivary amylase An enzyme in saliva that hydrolyzes starch to the disaccharide maltose.

salivary glands Accessory digestive glands found in vertebrates and some invertebrates; in humans there are three pairs.

salt An ionic compound consisting of an anion other than a hydroxide ion and a cation other than a hydrogen ion. A salt is formed by the reaction between an acid and a base.

saltatory conduction The transmission of a neural impulse along a myelinated neuron; ion activity at one node depolarizes the next node along the axon.

salt marsh A wetland dominated by grasses in which the salinity fluctuates between that of sea water and fresh water; salt marshes are usually located in estuaries.

saprobe See *decomposer*.

saprotroph (sap'-roh-trof) See *decomposer*.

sarcolemma (sar"-koh-lem'-mah) The muscle cell plasma membrane.

sarcomere (sar'-koh-meer) A segment of a striated muscle cell located between adjacent Z lines that serves as a unit of contraction.

sarcoplasmic reticulum The system of vesicles in a muscle cell that surrounds the myofibrils and releases calcium in muscle contraction; a modified endoplasmic reticulum.

satellites Subviral agents that require a helper virus to reproduce.

saturated fatty acid See *fatty acid*.

savanna (suh-van'-uh) A tropical grassland containing scattered trees; found in areas of low rainfall or seasonal rainfall with prolonged dry periods.

scaffolding proteins Nonhistone proteins that help maintain the structure of a chromosome.

scaffold proteins Proteins that organize groups of intracellular signaling molecules into signaling complexes.

scanning electron microscope (SEM) See *electron microscope*.

Schwann cells Supporting cells found in nervous tissue outside the central nervous system; produce the myelin sheath around peripheral neurons.

scientific method The process that scientists use to investigate the natural world; includes observing, recognizing a problem or stating a critical question, developing a hypothesis, making a prediction that can be tested, making further observations, performing experiments, interpreting results, and drawing conclusions that support or falsify the hypothesis.

scientific theory In science, a widely accepted explanation supported by a large body of observations and experiments. A scientific theory relates facts that appear unrelated; it predicts new facts and suggests new relationships. Compare with *hypothesis*.

sclera (skler'-ah) The outer coat of the eyeball; a tough, opaque sheet of connective tissue that protects the inner structures and helps maintain the rigidity of the eyeball.

sclereid (skler'-id) In plants, a sclerenchyma cell that is variable in shape but typically not long and tapered. Compare with *fiber*.

sclerenchyma (skler-en'-kim-uh) Cells that provide strength and support in the plant body, are often dead at maturity, and have extremely thick walls; includes fibers and sclereids.

scramble competition See *exploitation competition*.

scrotum (skroh'-tum) The external sac of skin found in most male mammals that contains the testes and their accessory organs.

sea grasses Flowering plants that have adapted to complete submersion in ocean water.

secondary consumer An animal that eats herbivores (primary consumers).

secondary growth An increase in the girth of a plant due to the activity of the vascular cambium and cork cambium; secondary growth results in the production of secondary tissues (i.e., wood and bark). Compare with *primary growth*.

secondary immune response The rapid production of antibodies induced by a second exposure to an antigen several days, weeks, or even months after the initial exposure. Compare with *primary immune response*.

secondary mycelium A dikaryotic mycelium formed by the fusion of two primary hyphae. Compare with *primary mycelium*.

secondary oocytes Haploid cells that undergo a second meiotic division, giving rise to a developing haploid ovum and a haploid polar body.

secondary productivity The amount of food molecules converted to biomass by consumers in an ecosystem over a given period. Compare with *primary productivity*.

secondary sex characteristics Changes that develop during puberty; in males, include growth of facial and body hair, muscle development, and the increase in vocal cord length and thickness that causes the voice to deepen; in females, include development of the breasts, broadening of the pelvis, and the development and distribution of muscle and fat responsible for the female body shape.

secondary spermatocytes Haploid cells that undergo a second meiotic division, giving rise to haploid spermatids.

secondary structure (of a protein) A regular geometric shape produced by hydrogen bonding between the atoms of the uniform polypeptide backbone; includes the alpha helix and the beta-pleated sheet. Compare with *primary*, *tertiary*, and *quaternary protein structure*.

secondary succession An ecological succession that takes place after some disturbance destroys the existing vegetation; soil is already present. See *succession*. Compare with *primary succession*.

second law of thermodynamics The physical law stating that the total amount of entropy in the universe continually increases. Compare with the *first law of thermodynamics*.

second messenger A substance (e.g., cyclic AMP or calcium ions) that relays a message from a signaling molecule (the *first messenger*) bound to a cell-surface receptor; leads to some change in the cell.

secretory vesicles Small cytoplasmic vesicles that move substances from an internal membrane system to the plasma membrane.

seed A plant reproductive body consisting of a young, multicellular plant and nutritive tissue (food reserves), enclosed by a seed coat.

seed coat The outer protective covering of a seed.

seed fern An extinct group of seed-bearing woody plants with fernlike leaves; seed ferns probably descended from progymnosperms and gave rise to cycads and possibly ginkgoes.

segmentation A body plan in which the body is divided into a series of compartments (segments).

segmentation genes In *Drosophila*, genes transcribed in the embryo that are responsible for generating a repeating pattern of body segments within the embryo and adult fly.

segregation, principle of The genetic principle, first noted by Gregor Mendel, that states that two alleles of a locus become separated into different gametes.

selectively permeable membrane A membrane that allows some substances to cross it more easily than others. Biological membranes are generally permeable to water but restrict the passage of many solutes.

self-incompatibility A genetic condition in which the pollen cannot fertilize the same flower or flowers on the same plant.

semelparous Having a single reproductive effort in a lifetime. Compare with *iteroparous*.

semen The fluid consisting of sperm suspended in various glandular secretions that is ejaculated from the penis during orgasm.

semicircular canals The passages in the vertebrate inner ear containing structures that control the sense of equilibrium (balance).

semiconservative replication See *DNA replication*.

semilunar valves Valves between the ventricles of the heart and the arteries that carry blood away from the heart; aortic and pulmonary valves.

seminal vesicles (1) In mammals, glandular sacs that secrete a component of semen (seminal fluid). (2) In some invertebrates, structures that store sperm.

seminiferous tubules (sem-ih-nif'-er-ous) Coiled tubules in the testes in which spermatogenesis takes place in male vertebrates.

senescence (se-nes'-cents) The aging process.

sense organ Sensory receptors along with other types of cells make up sense organs (e.g., eyes, ears, taste buds).

sensor In homeostasis, a receptor that detects a change (i.e., a deviation from the homeostatic state).

sensory adaptation The condition in which the response to a stimulus is reduced even though the stimulus continues at the same intensity.

sensory neuron A neuron that transmits an impulse from a receptor to the central nervous system.

sensory receptor The ending of an afferent neuron that is specialized to detect specific energy stimuli in its environment.

sepal (see'-pul) One of the outermost parts of a flower, usually leaflike in appearance, that protect the flower as a bud.

septum (pl., *septa*) A cross wall or partition. (1) In fungi, the walls that divide a hypha into cells. (2) In annelids, the partitions that separate the segments. (3) In birds and mammals, the wall that separates the two ventricles (and the two atria) of the heart.

sequencing See *DNA sequencing*.

serial endosymbiosis The hypothesis that certain organelles such as mitochondria and chloroplasts originated as symbiotic prokaryotes that lived inside other free-living prokaryotic cells.

serotonin A neurotransmitter of the biogenic amine group; important in mood and helps regulate the sleep–wake cycle.

serous membrane (sir'-us) An epithelial membrane that lines a body cavity that does not open to the outside of the body.

Sertoli cells (sur-tole'-ee) Supporting cells of the tubules of the testis.

serum Plasma minus fibrinogen and other clotting agents.

sessile (ses'-sile) Permanently attached to one location (e.g., coral animals).

setae (sing., *seta*) Bristlelike structures that aid in annelid locomotion.

set point A normal condition maintained by homeostatic mechanisms.

sex chromosome Chromosome that plays a role in sex determination.

sex pili See *pili*.

sex-influenced trait A genetic trait that is expressed differently in males and females.

sex-linked gene A gene carried on a sex chromosome. In mammals almost all sex-linked genes are borne on the X chromosome (i.e., are X-linked).

sexual dimorphism Marked phenotypic differences between the two sexes of the same species.

sexual isolation See *behavioral isolation*.

sexual reproduction A type of reproduction in which two gametes (usually, but not necessarily, contributed by two different parents) fuse to form a zygote. Compare with *asexual reproduction*.

sexual selection A type of natural selection that occurs when individuals of a species vary in their ability to compete for mates; individuals with reproductive advantages are selected over others of the same sex.

shade avoidance The tendency of plants that are adapted to high light intensities to grow taller when they are closely surrounded by other plants.

shared ancestral characters Traits that were present in an ancestral species that have remained essentially unchanged; suggest a distant common ancestor. Also called *plesiomorphic characters*. Compare with *shared derived characters*.

shared derived characters Homologous traits found in two or more taxa that are present in their most recent common ancestor but not in earlier common ancestors. Also called *synapomorphic characters*. Compare with *shared ancestral characters*.

shoot system The aboveground portion of a plant, such as the stem and leaves. Compare with *root system*.

short-day plant A plant that flowers in response to lengthening nights; also called *long-night plant*. Compare with *long-day*, *intermediate-day*, and *day-neutral plants*.

short-night plant See *long-day plant*.

short tandem repeats (STRs) Molecular markers that are short sequences of repetitive DNA; because STRs vary in length from one individual to another, they are useful in identifying individuals with a high degree of certainty.

short-term memory Memory that stores only about seven chunks of information and allows us

to recall that information only for seconds or for a few minutes. Compare with *long-term memory*.

sickle cell anemia An inherited form of anemia in which there is an abnormality in the hemoglobin beta chains; the inheritance pattern is autosomal recessive.

sieve tube Structure consisting of sieve tube elements joined end to end.

sieve tube elements Cells that conduct dissolved sugar in the phloem of flowering plants.

signal amplification The process by which a few signaling molecules can elicit major responses in the cell; the strength of each signaling molecule is magnified.

signaling molecule A molecule such as a hormone, local regulator, or neurotransmitter that transmits information when it binds to a receptor on the cell surface or within the cell.

signal-recognition particle (SRP) A protein–RNA complex that directs the ribosome–mRNA–polypeptide complex to the surface of the endoplasmic reticulum.

signal-recognition particle RNA See *signal-recognition particle (SRP)*.

signal transduction A process in which a cell converts and amplifies an extracellular signal into an intracellular signal that affects some function in the cell. Also see *cell signaling*.

sign stimulus Any stimulus that elicits a fixed action pattern in an animal.

silencer A regulatory element that associates with a eukaryotic gene and can decrease its transcription.

Silurian period See *Paleozoic era*.

simple diffusion See *diffusion*.

simple fruit A fruit that develops from a single ovary. Compare with *aggregate*, *accessory*, and *multiple fruits*.

simplest formula A type of chemical formula that gives the smallest whole-number ratio of the component atoms. Compare with *molecular formula* and *structural formula*.

single nucleotide polymorphisms (SNPs) Genetic variation among individuals in a population as measured by alleles of specific loci that differ by as little as a single nucleotide. The abbreviation is usually pronounced “snips.”

single-strand binding proteins (SSBs) Proteins involved in DNA replication that bind to single DNA strands and prevent the double helix from re-forming until the strands are copied.

sink habitat A lower-quality habitat in which local reproductive success is less than local mortality. Compare with *source habitat*.

sinoatrial (SA) node The mass of specialized cardiac muscle in which the impulse triggering the heartbeat originates; the pacemaker of the heart.

sister chromatids See *chromatid*.

sister taxa Groups of organisms that share a more recent common ancestor with one another than either taxon does with any other group shown on a cladogram.

skeletal muscle The voluntary striated muscle of vertebrates, so called because it usually is directly or indirectly attached to some part of the skeleton. Compare with *cardiac muscle* and *smooth muscle*.

slash-and-burn agriculture A type of agriculture in which tropical rain forest is cut down, allowed to dry, and burned. The crops that are planted immediately afterward thrive because the ashes provide nutrients; in a few years, however, the soil is depleted and the land must be abandoned.

slime layer A protective layer surrounding the cell wall of many prokaryotic species; more loosely attached to the cell wall than a capsule. See *capsule* (definition 3).

slow block to polyspermy See *cortical reaction*.

slow-oxidative fibers Muscle fibers specialized for endurance activities; they contract slowly, fatigue slowly, and obtain most of their ATP from aerobic respiration. Compare with *fast-oxidative fibers* and *fast-glycolytic fibers*.

small interfering RNAs (siRNAs) Double-stranded RNA molecules about 23 nucleotides in length that silence genes at the posttranscriptional level by selectively cleaving mRNA molecules with base sequences complementary to the siRNA. See also *microRNA (miRNA)*, *RNA interference (RNAi)*, and *piwi-associated RNA (piRNA)*.

small intestine Portion of the vertebrate digestive tract that extends from the stomach to the large intestine.

small nuclear ribonucleoprotein complexes (snRNPs) Aggregations of protein and small nuclear RNA (snRNA) that associate to form a spliceosome that binds to pre-mRNA in eukaryotes and catalyzes the excision of introns and splicing of exons. The abbreviation is usually pronounced “snurps.”

small nuclear RNA (snRNA) See *small ribonucleoprotein complexes (snRNPs)*.

small nucleolar RNA (snoRNA) RNA molecules involved in the processing of pre-ribosomal RNA during the formation of ribosome subunits in the nucleolus.

smooth ER See *endoplasmic reticulum*.

smooth muscle Involuntary muscle tissue that lacks transverse striations; found mainly in sheets surrounding hollow organs, such as the intestine. Compare with *cardiac muscle* and *skeletal muscle*.

SNP See *single nucleotide polymorphism*.

social behavior Interaction of two or more animals, usually of the same species.

social learning Learning through observing others and imitating them.

society A group of individuals belonging to the same species and often closely related; an organized society is an actively cooperating group.

sociobiology The branch of biology that focuses on the evolution of social behavior through natural selection.

sodium–potassium pump ATP-binding cassette transporter in the plasma membrane of all animal cells; uses ATP energy to transport Na⁺ out of the cell and K⁺ into the cell.

soil erosion The wearing away or removal of soil from the land; although soil erosion occurs naturally from precipitation and runoff, human activities (such as clearing the land) accelerate it.

solute A dissolved substance. Compare with *solvent*.

solvent Substance capable of dissolving other substances. Compare with *solute*.

somatic cell In animals, a cell of the body not involved in formation of gametes. Compare with *germ line cell*.

somatic division (of the PNS) That part of the vertebrate peripheral nervous system that keeps the body in adjustment with the external environment; includes sensory receptors on the body surface and within the muscles, and the nerves that link them with the central nervous system. Compare with *autonomic division (of the PNS)*.

somatomedins See *insulin-like growth factors*.

somatotropin See *growth hormone*.

somites A series of paired blocks of mesoderm that develop on each side of the notochord in cephalochordates and vertebrates. Somites define the segmentation of the embryo, and in vertebrates, they give rise to the vertebrae, ribs, and certain skeletal muscles.

sonogram See *ultrasound imaging*.

soredium (sor-id'e-um) (pl., *soredia*) In lichens, a type of asexual reproductive structure that consists of a cluster of algal cells surrounded by fungal hyphae.

sorus (soh'rus) (pl., *sori*) In ferns, a cluster of spore-producing sporangia.

source habitat A good habitat in which local reproductive success is greater than local mortality. Surplus individuals in a source habitat may disperse to other habitats. Compare with *sink habitat*.

Southern blot A technique in which DNA fragments, previously separated by gel electrophoresis, are transferred to a nitrocellulose or nylon membrane and detected by autoradiography or chemical luminescence. Compare with *Northern blot* and *Western blot*.

spatial summation The summing of several postsynaptic potentials resulting when several presynaptic neurons release neurotransmitter simultaneously. Compare with *temporal summation*.

speciation Evolution of a new species.

species According to the biological species concept, one or more populations whose members are capable of interbreeding in nature to produce fertile offspring and do not interbreed with members of other species. Compare with *phylogenetic species concept*.

species diversity A measure of the relative importance of each species within a community; represents a combination of species richness and species evenness.

species evenness Relative abundance of one species compared to other species in a community.

species richness The number of species in a community.

specific epithet The second part of the name of a species; designates a specific species belonging to that genus.

specific heat The amount of heat energy that must be supplied to raise the temperature of 1 g of a substance 1°C.

specific immune responses See *adaptive immune responses*.

specific immunity See *adaptive immune responses*.

sperm The motile male gamete of animals and some plants and protists; also called a *spermatozoan*.

spermatid (spur'-ma-tid) An immature sperm cell.

spermatocyte (spur-mah'-toh-site) A meiotic cell that gives rise to spermatids and ultimately to mature sperm cells.

spermatogenesis (spur'-mah-toh-jen'-eh-sis) The production of male gametes (sperm) by meiosis and subsequent cell differentiation. Compare with *oogenesis*.

spermatogonia Undifferentiated cells in the testes that give rise to primary spermatocytes.

spermatozoan (spur-mah-toh-zoh'-un) See *sperm*.

sphincter (sfink'-tur) A group of circularly arranged muscle fibers, the contractions of which close an opening (e.g., the pyloric sphincter at the exit of the stomach).

spicules (spik'-yuls) Slender skeletal spikes made of calcium carbonate or silica; found in sponges and some other animals.

spinal cord In vertebrates, the dorsal, tubular nerve cord.

spinal nerves In vertebrates, the nerves that emerge from the spinal cord; there are 31 pairs in humans.

spindle See *mitotic spindle*.

spine A leaf that is modified for protection, such as a cactus spine.

spiracle (speer'-ih-kl) An opening for gas exchange, such as the opening of a trachea on the body surface of an insect.

spiral cleavage A distinctive spiral pattern of blastomere production in an early protostome embryo. Compare with *radial cleavage*.

spirillum (pl., *spirilla*) A long, rigid, helical bacterium. Compare with *spirochete*, *vibrio*, *bacillus*, and *coccus*.

spirochete A long, flexible, helical bacterium. Compare with *spirillum*, *vibrio*, *bacillus*, and *coccus*.

spleen An abdominal organ located just below the diaphragm that removes worn-out blood cells and bacteria from the blood and plays a role in immunity.

spliceosome A large ribonucleoprotein particle that catalyzes the reactions that remove introns from pre-mRNA.

spongocoel (spon'-jo-seel) The central cavity of a sponge.

spongy bone Consists of a network of thin strands of bone; provides mechanical strength.

spongy mesophyll (mez'-oh-fil) The loosely arranged mesophyll cells near the lower epidermis in certain leaves. Compare with *palisade mesophyll*.

spontaneous reaction See *exergonic reaction*.

sporangium (spor-an'-jee-um) (pl., *sporangia*) A spore case, found in plants, certain protists, and fungi.

spore A reproductive cell that gives rise to individual offspring in plants, fungi, and certain algae and protozoa.

sporophyll (spor'-oh-fil) A leaflike structure that bears spores.

sporophyte generation (spor'-oh-fite) The 2n, spore-producing stage in the life cycle of a plant. Compare with *gametophyte generation*.

sporozoite The infective sporelike state in apicomplexans.

spring turnover Mixing of temperate lake waters in spring, caused by rising temperatures, in which surface water sinks to the bottom and bottom water rises to the surface. Compare with *fall turnover*.

stabilizing selection Natural selection that acts against extreme phenotypes and favors intermediate variants; associated with a population well adapted to its environment. Compare with *directional selection* and *disruptive selection*.

stamen (stay'-men) The male part of a flower; consists of a filament and anther.

standing-water ecosystem A lake or pond ecosystem.

starch A polysaccharide composed of alpha glucose subunits; made by plants for energy storage.

start codon The codon AUG, which signals the beginning of translation of messenger RNA. Compare with *stop codon*.

stasis Long periods in the fossil record in which there is little or no evolutionary change.

statocyst (stat'-oh-sist) An invertebrate sense organ containing one or more granules (statoliths); senses gravity and motion.

statoliths (stat'-uh-liths) Granules of loose sand or calcium carbonate found in statocysts.

stele The cylinder in the center of roots and stems that contains the vascular tissue; also called *vascular cylinder*.

stem cell A relatively undifferentiated cell capable of repeated cell division. At each division at least one of the daughter cells usually remains a stem cell, whereas the other may differentiate as a specific cell type. Compare with *embryonic stem cell (ES cell)* and *induced pluripotent stem cell (iPSC)*.

stereocilia Hairlike projections of hair cells; microvilli that contain actin filaments.

sterilization A procedure that renders an individual incapable of producing offspring; the most common surgical procedures are vasectomy in the male and tubal ligation in the female.

steroid hormones Hormones, such as insect molting hormone, cortisol, and male/female sex hormones, that are derived from cholesterol.

steroids (steer'-oids) Complex molecules containing carbon atoms arranged in four attached rings, three of which contain six carbon atoms each and the fourth of which contains five (e.g., cholesterol and certain hormones, including the male and female sex hormones of vertebrates).

stigma The portion of the carpel where pollen grains land during pollination (and before fertilization).

stipe A short stalk or stemlike structure that is a part of the body of certain multicellular algae.

stipule (stip'-yule) One of a pair of scalelike or leaflike structures found at the base of certain leaves.

stolon (stow'-lon) An aboveground, horizontal stem with long internodes; stolons often form buds that develop into separate plants (e.g., strawberry); also called a *runner*.

stomach Muscular region of the vertebrate digestive tract, extending from the esophagus to the small intestine.

stomata (sing., *stoma*) Small pores located in the epidermis of plants that provide for gas exchange for photosynthesis; each stoma is flanked by two guard cells, which are responsible for its opening and closing.

stop codon Any of the three codons in mRNA that do not code for an amino acid (UAA, UAG, or UGA) but signal the termination of translation. Compare with *start codon*.

stramenopiles Protists that have motile cells with two flagella, one of which has tiny hairlike projections off the shaft; include water molds, diatoms, golden algae, and brown algae. See *chromalveolates*; compare with *alveolates*.

stratosphere The layer of the atmosphere between the troposphere and the mesosphere. It contains a thin ozone layer that protects life by filtering out much of the sun's ultraviolet radiation.

stratum basale (strat'-um bah-say'-lee) The deepest sublayer of the human epidermis, consisting of cells that continuously divide. Compare with *stratum corneum*.

stratum corneum The most superficial sublayer of the human epidermis. Compare with *stratum basale*.

strobilus (stroh'-bil-us) (pl., *strobili*) In certain plants, a conelike structure that bears spore-producing sporangia.

stroke volume The volume of blood pumped by one ventricle during one contraction.

stroma A fluid space of the chloroplast, enclosed by the chloroplast inner membrane and surrounding the thylakoids; site of the reactions of the Calvin cycle.

stromatolite (stroh-mat'-oh-lite) A columnlike rock that consists of many minute layers of prokaryotic cells, usually cyanobacteria.

structural formula A type of chemical formula that shows the spatial arrangement of the atoms in a molecule. Compare with *simplest formula* and *molecular formula*.

structural isomer One of two or more chemical compounds having the same chemical formula but differing in the covalent arrangement of their atoms (e.g., glucose and fructose).

style The neck connecting the stigma to the ovary of a carpel.

subsidiary cell In plants, a structurally distinct epidermal cell associated with a guard cell.

subsistence agriculture Farming practice in which crops are grown only to meet the needs of the farm family.

substance P A peptide neurotransmitter released by certain sensory neurons in pain pathways; signals the CNS regarding pain; also stimulates other structures, including smooth muscle in the digestive tract.

substrate A substance on which an enzyme acts; a reactant in an enzymatically catalyzed reaction.

substrate-level phosphorylation The formation of ATP by the transfer of a phosphate to ADP from a phosphorylated intermediate.

subviral agents Infective agents that are smaller and simpler than viruses; include satellites, viroids, and prions.

succession The sequence of changes in the species composition of a community over time. See *primary succession* and *secondary succession*.

sucker A shoot that develops adventitiously from a root; a type of asexual reproduction.

sulcus (sul'-kus) (pl., *sulci*) A groove, trench, or depression, especially one occurring on the surface of the brain, separating the convolutions.

sulfhydryl group Functional group abbreviated —SH; found in organic compounds called thiols.

summation The process of adding together excitatory postsynaptic potentials (EPSPs).

sum rule The rule for combining the probabilities of mutually exclusive events by adding their individual probabilities. Compare with *product rule*.

superior vena cava In humans, a very large vein that delivers blood from the upper part of the body to the right atrium. Compare with *inferior vena cava*.

suppressor T cell T lymphocyte that suppresses the immune response.

suprachiasmatic nucleus Main biological clock; located in the hypothalamus. Important in setting circadian rhythms.

supraorbital ridge (soop''-rah-or'-bit-ul) The prominent bony ridge above the eye socket; ape skulls have prominent supraorbital ridges.

surface tension The attraction that the molecules at the surface of a liquid may have for one another.

survivorship The probability that a given individual in a population or cohort will survive to a particular age; usually presented as a survivorship curve.

survivorship curve A graph of the number of surviving individuals of a cohort, from birth to the maximum age attained by any individual.

suspensor (suh-spen'-sur) In plant embryo development, a multicellular structure that anchors the embryo and aids in nutrient absorption from the endosperm.

sustainability See *environmental sustainability*.

swim bladder The hydrostatic organ in bony fishes that permits the fish to hover at a given depth.

symbionts The partners in a symbiotic relationship.

symbiosis (sim-bee-oh'-sis) An intimate relationship between two or more organisms of different species. See *commensalism*, *mutualism*, and *parasitism*.

sympathetic system A system of the autonomic division of the nervous system; its general effect is to mobilize energy, especially during stressful situations; prepares the body for a fight, flight, or freeze response. Compare with *parasympathetic system*.

sympatric speciation (sim-pa'-trik) The evolution of a new species within the same geographic region as the parental species. Compare with *allopatric speciation*.

symplast A continuum consisting of the cytoplasm of many plant cells, connected from one cell to the next by plasmodesmata. Compare with *apoplast*.

symporter Membrane carrier protein that transports two types of substances in one direction. Compare with *uniporter* and *antiporter*.

synapomorphic characters See *shared derived characters*.

synapse (sin'-aps) The junction between two neurons or between a neuron and an effector (muscle or gland).

synapsids (sin-ap'-sids) Members of a clade of amniotes in which the skull has one pair of temporal openings; include the extinct therapsid reptiles and mammals. Compare with *diapsids*.

synapsis (sin-ap'-sis) The process of physical association of homologous chromosomes during prophase I of meiosis.

synaptic enhancement An increase in neurotransmitter release thought to occur as a result of calcium ion accumulation inside the presynaptic neuron.

synaptic plasticity The ability of synapses to change in response to certain types of stimuli. Synaptic changes occur during learning and memory storage.

synaptonemal complex The structure, visible with the electron microscope, produced when homologous chromosomes undergo synapsis.

synthesis phase See *S phase*.

systematics The scientific study of the diversity of organisms and their evolutionary relationships. Taxonomy is an aspect of systematics. See *taxonomy*.

systemic acquired resistance (SAR) A defensive response in infected plants that helps fight infection and promote wound healing.

systemic anaphylaxis A rapid, widespread allergic reaction that can lead to death.

systemic circulation The part of the circulatory system that delivers blood to and from the tissues and organs of the body. Compare with *pulmonary circulation*.

systems biology A field of biology that synthesizes knowledge of many small parts to understand the whole. Also referred to as *integrative biology* or *integrative systems biology*.

systole (sis'-tuh-lee) The phase of the cardiac cycle when the heart is contracting. Compare with *diastole*.

T cell (T lymphocyte) The type of white blood cell responsible for a wide variety of immune functions, particularly cell-mediated immunity. T cells are processed in the thymus. Compare with *B cell*.

T cytotoxic cells (T_c) T cells that recognize and destroy cells infected with viruses or other intracellular pathogens; also destroy cancer cells and other pathogenic cells. Also known as *CD8 T cells* and *killer T cells*.

T helper cells (T_H) T cells that activate B cells (B lymphocytes) and stimulate T cytotoxic cell production. Also known as *CD4 T cells*.

T tubules Transverse tubules; system of inward extensions of the muscle fiber plasma membrane.

taiga (tie'-gah) See *boreal forest*.

taproot system A root system consisting of a prominent main root with smaller lateral roots branching off it; a taproot develops directly from the embryonic radicle. Compare with *fibrous root system*.

target cell or tissue A cell or tissue with receptors that bind a hormone.

TATA box A component of a eukaryotic promoter region; consists of a sequence of bases located about 30 base pairs upstream from the transcription initiation site.

taxon A formal taxonomic group at any level (e.g., phylum or genus).

taxonomy (tax-on'-ah-mee) The science of naming, describing, and classifying organisms; see *systematics*.

Tay-Sachs disease A serious genetic disease in which abnormal lipid metabolism in the brain causes mental deterioration in affected infants and young children; inheritance pattern is autosomal recessive.

T-cell receptors (TCR) The receptors on T cells that recognize specific antigens.

tectorial membrane (tek-tor'-ee-ul) The roof membrane of the organ of Corti in the cochlea of the ear.

telencephalon See *forebrain*.

telolecithal egg An egg with a large amount of yolk, concentrated at the vegetal pole. Compare with *isolecithal egg*.

telomerase A special DNA replication enzyme that can lengthen telomeric DNA by adding repetitive nucleotide sequences to the ends of eukaryotic chromosomes; typically present in cells that divide an unlimited number of times.

telomeres The protective end caps of chromosomes that consist of short, simple, non-coding DNA sequences that repeat many times.

telophase (teel'-oh-faze or tel'-oh-faze) The last stage of mitosis and of meiosis I and II when, having reached the poles, chromosomes become decondensed, and a nuclear envelope forms around each group.

telophase I See *meiosis* and *meiosis I*.

telophase II See *meiosis* and *meiosis II*.

temperate deciduous forest A forest biome that occurs in temperate areas where annual precipitation ranges from about 75 cm to 125 cm.

temperate grassland A grassland characterized by hot summers, cold winters, and less rainfall than is found in a temperate deciduous forest biome.

temperate phage See *temperate virus*.

temperate rain forest A coniferous biome characterized by cool weather, dense fog, and high precipitation (e.g., the north Pacific coast of North America).

temperate virus A virus that integrates into the host DNA as a prophage.

temperature The average kinetic energy of the particles in a sample of a substance.

template A pattern or guide (e.g., one strand of DNA functions as a template for the synthesis of a complementary DNA or RNA strand).

temporal isolation A prezygotic reproductive isolating mechanism in which genetic exchange is prevented between similar species because they reproduce at different times of the day, season, or year.

temporal lobes Region of the cerebrum that contains the auditory areas.

temporal summation The summing of several postsynaptic potentials produced when a single presynaptic neuron fires multiple times in rapid succession. Compare with *spatial summation*.

tendon A connective tissue structure that joins a muscle to another muscle, or a muscle to a bone. Tendons transmit the force generated by a muscle.

tendril A leaf or stem that is modified for holding or attaching onto objects.

tension-cohesion model The mechanism by which water and dissolved inorganic minerals are thought to be transported in xylem; water is pulled upward under tension because of transpiration while maintaining an unbroken column in xylem

because of cohesion; also called *transpiration-cohesion model*.

teratogen Any agent capable of interfering with normal morphogenesis in an embryo, thereby causing malformations; examples include radiation, certain chemicals, and certain infectious agents.

terminal bud A bud at the tip of a stem. Compare with *axillary bud*.

termination (of protein synthesis) The final stage of protein synthesis, which occurs when a termination (stop) codon is reached, causing the completed polypeptide chain to be released from the ribosome. See *initiation* and *elongation*.

termination codon See *stop codon*.

territoriality Behavior pattern in which one organism (usually a male) stakes out a territory of its own and defends it against intrusion by other members of the same species and sex.

tertiary consumer See *carnivore*.

tertiary structure (of a protein) (tur'-she-air'-ee) The overall three-dimensional shape of a polypeptide that is determined by interactions involving the amino acid side chains. Compare with *primary*, *secondary*, and *quaternary protein structure*.

test A shell.

test cross The genetic cross in which either an F₁ individual, or an individual of unknown genotype, is mated to a homozygous recessive individual.

testis (tes'-tis) (pl., *testes*) The male gonad that produces sperm and the male hormone testosterone; in humans and certain other mammals, the testes are located in the scrotum.

testosterone (tes-tos'-ter-own) The principal male sex hormone (androgen); a steroid hormone produced by the interstitial cells of the testes; stimulates spermatogenesis and is responsible for primary and secondary sex characteristics in the male.

tetrad The chromosome complex formed by the synopsis of a pair of homologous chromosomes (i.e., four chromatids) during meiotic prophase I.

tetrapods (tet'-rah-podz) Four-limbed vertebrates: the amphibians, reptiles, birds, and mammals.

thalamus (thal'-uh-mus) The part of the vertebrate brain that serves as a main relay center, transmitting information between the spinal cord and the cerebrum.

thallus (thal'-us) (pl., *thalli*) The simple body of an alga, fungus, or nonvascular plant that lacks roots, stems, or leaves (e.g., a liverwort thallus or a lichen thallus).

theca cells The layer of connective tissue cells that surrounds the granulosa cells in an ovarian follicle; stimulated by luteinizing hormone (LH) to produce androgens, which are converted to estrogen in the granulosa cells.

theory See *scientific theory*.

therapods Bipedal, saurischian dinosaurs that were predators; included *Tyrannosaurus*.

therapsids (ther-ap'-sidz) A group of mammal-like reptiles of the Permian period; gave rise to the mammals.

thermal stratification The marked layering (separation into warm and cold layers) of temperate lakes during the summer. See *thermocline*.

thermocline (thur'-moh-kline) A marked and abrupt temperature transition in temperate lakes between warm surface water and cold deeper water. See *thermal stratification*.

thermodynamics Principles governing energy transfer (often expressed in terms of heat transfer). See *first law of thermodynamics* and *second law of thermodynamics*.

thermoreceptor A sensory receptor that responds to heat.

thermoregulation The process of maintaining body temperature within certain limits despite changes in the surrounding temperature.

thigmomorphogenesis (thig"-moh-mor-foh-jen'-uh-sis) An alteration of plant growth in response to mechanical stimuli, such as wind, rain, hail, and contact with passing animals.

thigmotropism (thig"-moh-troh'-pizm) Plant growth in response to contact with a solid object, such as the twining of plant tendrils.

threatened species A species in which the population is small enough for it to be at risk of becoming extinct throughout all or part of its range but not so small that it is in imminent danger of extinction. Compare with *endangered species*.

threshold level The potential that a neuron or other excitable cell must reach for an action potential to be initiated.

thrombocytes Small, nucleated cells that function in blood clotting; found in most vertebrates other than mammals. Also see *platelets*.

thylakoid lumen See *thylakoids*.

thylakoids (thy'-lah-koidz) An interconnected system of flattened, saclike, membranous structures inside the chloroplast; the thylakoid membranes contain chlorophyll and enclose an internal space, the thylakoid lumen.

thymine (thy'-meen) A nitrogenous pyrimidine base found in DNA.

thymosin Hormone produced by the thymus gland that plays a role in immune responses.

thymus gland (thy'-mus) An endocrine gland that functions as part of the lymphatic system; processes T cells; important in cell-mediated immunity.

thyroid gland An endocrine gland that lies anterior to the trachea and releases hormones that regulate the rate of metabolism.

thyroid hormones Hormones, including thyroxine (T₄) and triiodothyronine (T₃), secreted by the thyroid gland; stimulate rate of metabolism.

thyroid-releasing hormone (TRH) Hormone secreted by the hypothalamus to increase thyroid hormone secretion when mammals are exposed to extreme cold. Compare with *thyroid-stimulating hormone (TSH)*.

thyroid-stimulating hormone (TSH) Hormone secreted by the anterior pituitary gland to regulate thyroid hormone secretion. Compare with *thyroid-releasing hormone (TRH)*.

thyroxine (T₄) See *thyroid hormones*.

tidal volume The volume of air moved into and out of the lungs with each normal resting breath.

tight junctions Specialized structures that form between some animal cells, producing a tight seal that prevents materials from passing through the spaces between the cells.

tissue A group of closely associated, similar cells that work together to carry out specific functions.

tissue culture The growth of tissue or cells in a synthetic growth medium under sterile conditions.

tissue engineering A developing technology that is striving to grow human tissues and organs (for transplantation) in cell cultures.

tissue fluid See *interstitial fluid*.

tolerance A decreased response to a drug over time.

Toll-like receptors A type of pattern recognition receptor. Cell-surface receptors on several cell types that recognize pathogen-associated molecular patterns (certain common features of classes of pathogens). See also *pathogen-associated molecular patterns (PAMPs)*.

tonoplast The membrane surrounding a vacuole.

top-down processes Control of ecosystem function by trophic interactions, particularly from the highest trophic level. Compare with *bottom-up processes*.

topoisomerases (toe-poe-eye-sahm'-er-ases) Enzymes that relieve twists and kinks in a DNA molecule by breaking and rejoining the strands.

torpor An energy-conserving state of low metabolic rate and inactivity. See *estivation* and *hibernation*.

torsion The twisting of the visceral mass characteristic of gastropod mollusks.

total fertility rate The average number of children born to a woman during her lifetime.

totipotent (toh-ti-poh'-tent) A term describing a cell or nucleus that contains the complete set of genetic instructions required to direct the normal development of an entire organism. Compare with *pluripotent*.

trace element An element required by an organism in very small amounts.

trachea (tray'-kee-uh) (pl., *tracheae*) (1) Principal thoracic air duct of terrestrial vertebrates; windpipe. (2) One of the microscopic air ducts (or tracheal tubes) branching throughout the body of most terrestrial arthropods and some terrestrial mollusks.

tracheal tubes See *trachea*.

tracheid (tray'-kee-id) A type of water-conducting and supporting cell in the xylem of vascular plants.

tract A bundle of nerve fibers within the central nervous system.

trait A heritable difference.

transcription The synthesis of RNA from a DNA template.

transcriptional-level control Regulation of gene expression by controlling RNA synthesis. Compare with *translational-level control*, *posttranslational control*, and *posttranscriptional control*.

transcription factors DNA-binding proteins that regulate transcription in eukaryotes; include positively acting activators and negatively acting repressors.

transduction (1) The transfer of a genetic fragment from one cell to another (e.g., from one bacterium to another) by a virus. (2) In the nervous system, the conversion of energy of a stimulus to electrical signals.

transfer RNA (tRNA) RNA molecules that bind to specific amino acids and serve as adapter

molecules in protein synthesis. The tRNA anticodons bind to complementary mRNA codons.

transformation (1) The incorporation of genetic material into a cell, thereby changing its phenotype. (2) The conversion of a normal cell to a cancer cell (called a malignant transformation).

transgenic organism A plant or animal that has foreign DNA incorporated into its genome.

translation The conversion of information provided by mRNA into a specific sequence of amino acids in a polypeptide chain; process also requires transfer RNA and ribosomes.

translational control See *translational-level control*.

translational-level control Regulation of gene expression by controlling the translation of mRNA into protein. Compare with *transcriptional-level control*, *posttranscriptional control*, and *posttranslational control*.

translocation (1) The movement of organic materials (dissolved food) in the phloem of a plant. (2) Chromosome abnormality in which part of one chromosome has become attached to another. (3) Part of the elongation cycle of protein synthesis in which a transfer RNA attached to the growing polypeptide chain is transferred from the A site to the P site.

transmembrane protein An integral membrane protein that spans the lipid bilayer.

transmission electron microscope (TEM) See *electron microscope*.

transpiration The loss of water vapor from the aerial surfaces of a plant (i.e., leaves and stems).

transpiration-cohesion model See *tension-cohesion model*.

transport vesicles Small cytoplasmic vesicles that move substances from one membrane system to another.

transposon (tranz-poze'-on) A DNA segment that is capable of moving from one chromosome to another or to different sites within the same chromosome; also called a *mobile genetic element*.

transverse tubules See *T tubules*.

tree line Zone at high altitudes or high latitudes beyond which trees are unable to grow.

triacylglycerol (try-ace"-il-glis'-er-ol) The main storage lipid of organisms, consisting of a glycerol combined chemically with three fatty acids; also called *triglyceride*. Compare with *monoacylglycerol* and *diacylglycerol*.

Triassic period See *Mesozoic era*.

tricarboxylic acid (TCA) cycle See *citric acid cycle*.

trichome (try'-kohm) A hair or other appendage growing out from the epidermis of a plant.

tricuspid valve See *atrioventricular valve*.

triglyceride See *triacylglycerol*.

triiodothyronine (T₃) See *thyroid hormones*.

triose A sugar molecule containing three carbons.

triple-gene fusion The fusion of three separate genes into a single unit early in the course of eukaryote evolution; provides evidence of a bifurcation; characteristic of unikonts.

triplet A sequence of three nucleotides that serves as the basic unit of genetic information.

triplet code The sequences of three nucleotides that compose the codons, the units of genetic

information in mRNA that specify the order of amino acids in a polypeptide chain.

triploblastic (trip-lo-blas'-tik) An animal body plan in which there are three embryonic tissue layers, the ectoderm, mesoderm, and endoderm. Compare with *diploblastic*.

trisomy (try'-sohm-ee) A type of aneuploidy in which an individual has two copies of each chromosome except for one, which has three copies; designated $2n + 1$. Compare with *monosomy* and *disomy*.

trisomy 21 See *Down syndrome*.

trochophore larva (troh'-koh-for) A larval form found in mollusks and many polychaetes.

trophic level (troh'-fik) Each sequential step of matter and energy in a food web, from producers to primary, secondary, or tertiary consumers; each organism is assigned to a trophic level based on its primary source of nourishment.

trophoblast (troh'-foh-blast) The outer cell layer of a late blastocyst, which in placental mammals gives rise to the chorion and to the fetal contribution to the placenta.

tropical dry forest A tropical forest where enough precipitation falls to support trees but not enough to support the lush vegetation of a tropical rain forest; often occurs in areas with pronounced rainy and dry seasons.

tropical rain forest A lush, species-rich forest biome that occurs in tropical areas where the climate is very moist throughout the year. Tropical rain forests are also characterized by old, infertile soils.

tropic hormone (trow'-pic) A hormone that regulates the secretion of another hormone.

tropism (troh'-pizm) In plants, a directional growth response that is elicited by an environmental stimulus.

tropomyosin (troh-poh-my'-oh-sin) A muscle protein involved in regulation of contraction.

troponin (tro-po'-nun) A regulatory protein in the actin filaments of muscle fibers.

true-breeding Refers to a genetic strain of an organism in which all individuals are homozygous at the loci under consideration.

trypsin (trip'-sin) A pancreatic enzyme that digests polypeptides to short peptides.

tube feet Structures characteristic of echinoderms; function in locomotion and feeding.

tuber A thickened end of a rhizome that is fleshy and enlarged for food storage (e.g., white potato).

tubular reabsorption The process by which epithelial cells lining the renal tubules selectively reabsorb about 99% of the glomerular filtrate and return it to the blood; an essential step in adjusting the chemical composition of the blood.

tubular secretion The selective transfer of substances from the blood in the peritubular capillaries into the renal tubule.

tubulin See *microtubules*.

tubular transport maximum (Tm) The maximum rate at which a substance is reabsorbed from the renal tubules of the kidney.

tumor A mass of tissue that grows in an uncontrolled manner; a neoplasm.

tumor necrosis factors (TNFs) Cytokines that kill tumor cells and stimulate immune cells to initiate an inflammatory response.

tumor suppressor gene A gene (also known as an *anti-oncogene*) whose normal role is to block cell division in response to certain growth-inhibiting factors; when mutated, may contribute to the formation of a cancer cell. Compare with *oncogene*.

tundra (tun'-dra) A treeless biome between the boreal forest in the south and the polar ice cap in the north that consists of boggy plains covered by lichens and small plants. Also called *arctic tundra*. Compare with *alpine tundra*.

tunicates Chordates belonging to subphylum Urochordata; sea squirts.

turgor pressure (tur'-gor) Hydrostatic pressure that develops within a walled cell and presses outward against the plasma membrane.

Turner syndrome An inherited condition in which only one sex chromosome (an X chromosome) is present in cells; karyotype is designated X0; affected individuals are sterile females.

two-point test cross A genetic cross used to test for linkage; individuals heterozygous at two loci are crossed with individuals who are homozygous recessive at those loci.

tyrosine kinase An enzyme that phosphorylates the tyrosine part of proteins.

tyrosine kinase receptor A plasma membrane receptor that phosphorylates the tyrosine part of proteins; when a ligand binds to the receptor, the conformation of the receptor changes and it may phosphorylate itself as well as other molecules; important in immune function and serves as a receptor for insulin.

ubiquitin A small eukaryotic regulatory polypeptide that can be covalently bonded to proteins, targeting the protein for destruction and recycling. Also used to regulate protein activities.

ultimate causes (of behavior) Evolutionary explanations for why a certain behavior occurs. Compare with *proximate causes (of behavior)*.

ultrasound imaging A technique in which high-frequency sound waves (ultrasound) are used to provide an image (sonogram) of an internal structure.

ultrastructure The fine detail of a cell, generally only observable by use of an electron microscope.

umbilical cord In eutherian mammals, the organ that connects the embryo to the placenta.

uniform dispersion The spatial distribution pattern of a population in which individuals are regularly spaced. Compare with *random dispersion* and *clumped dispersion*.

unikonts One of two main clades of all eukaryotes; had a common ancestor with a single posterior flagellum. See *opisthokonts* and *amoebzoa*. Compare with *bikonts*.

uniporter Membrane carrier protein that transports one type of substance in one direction. Compare with *symporter* and *antiporter*.

uniramous appendages Unbranched appendages. Compare with *biramous appendages*.

unsaturated fatty acid See *fatty acid*.

upwelling An upward movement of water that brings nutrients from the ocean depths to the surface. Where upwelling occurs, the ocean is very productive.

uracil (yur'-ah-sil) A nitrogenous pyrimidine base found in RNA.

urea (yur-ee'-ah) The principal nitrogenous excretory product of mammals; one of the water-soluble end products of protein metabolism.

ureter (yur'-ih-tur) One of the paired tubular structures that conducts urine from the kidney to the bladder.

urethra (yoo-ree'-thruh) The tube that conducts urine from the bladder to the outside of the body.

uric acid (yoor'-ik) The principal nitrogenous excretory product of insects, birds, and reptiles; a relatively insoluble end product of protein metabolism; also occurs in mammals as an end product of purine metabolism.

urinary bladder An organ that receives urine from the ureters and temporarily stores it.

urinary system The body system in vertebrates that consists of the kidneys, urinary bladder, and associated ducts.

urochordates A subphylum of chordates; includes the tunicates.

uterine tube (yoo'-tur-in) See *oviduct*.

uterus (yoo'-tur-us) The hollow, muscular organ of the female reproductive tract in which the fetus undergoes development.

utricle The structure within the vestibule of the vertebrate inner ear that, along with the saccule, houses the receptors of static equilibrium.

vaccine (vak-seen') A commercially produced, weakened or killed antigen associated with a particular disease that stimulates the body to make antibodies.

vacuole (vak'-yoo-ole) A fluid-filled, membrane-enclosed sac found within the cytoplasm; may function in storage, digestion, or water elimination.

vagina The elastic, muscular tube, extending from the cervix to its external opening, that receives the penis during heterosexual intercourse and serves as the birth canal.

valence electrons The electrons in the outer electron shell, known as the *valence shell*, of an atom; in the formation of a chemical bond, an atom can accept electrons into its valence shell or donate or share valence electrons.

van der Waals interactions Weak attractive forces between atoms; caused by interactions among fluctuating charges.

vascular cambium A lateral meristem that produces secondary xylem (wood) and secondary phloem (inner bark). Compare with *cork cambium*.

vascular cylinder See *stele*.

vascular tissue system The tissues specialized for translocation of materials throughout the plant body (i.e., the xylem and phloem).

vas deferens (vas def'-ur-enz) (pl., *vasa deferentia*) One of the paired sperm ducts that connects the epididymis of the testis to the ejaculatory duct.

vasoconstriction Narrowing of the diameter of blood vessels.

vasodilation Expansion of the diameter of blood vessels.

vector (1) Any carrier or means of transfer. (2) Agent (e.g., a plasmid or virus) that transfers genetic information. (3) Agent that transfers a parasite from one host to another.

vegetal pole The yolk pole of a vertebrate or echinoderm egg. Compare with *animal pole*.

vein (1) A blood vessel that carries blood from the tissues toward a chamber of the heart (compare with *artery*). (2) A strand of vascular tissue that is part of the network of conducting tissue in a leaf; also called a *vascular bundle*.

veliger larva The larval stage of many marine gastropods (snails) and bivalves (e.g., clams); often is a second larval stage that develops after the trochophore larva.

ventilation The process of actively moving air or water over a respiratory surface.

ventral Toward the lowermost surface or belly of an animal. Compare with *dorsal*.

ventricle (1) One of four interconnected chambers in the brain through which cerebrospinal fluid flows. (2) One of the chambers of the heart that receives blood from an atrium and pumps blood into arteries.

vertebrae (vert'-teh-bray) (sing., *vertebra*) The bones that make up the spine.

vertebral column The spine, the rigid, bony structure in the midline of the back; composed of vertebrae.

vertebrates A subphylum of chordates that includes fishes, amphibians, reptiles, birds, and mammals; possess a bony vertebral column.

vertical gene transfer The transfer of genetic material from parent to offspring. Compare with *horizontal gene transfer*.

vesicle (ves'-ih-kl) Any small sac, especially a small, spherical, membrane-enclosed compartment, within the cytoplasm.

vessel In plants, a stack of vessel elements.

vessel element A type of water-conducting cell in the xylem of vascular plants; a stack of vessel elements is a vessel.

vestibular apparatus Collectively, the saccule, utricle, and semicircular canals of the inner ear.

vestigial (ves-tij'-ee-ul) Rudimentary; an evolutionary remnant of a formerly functional structure.

vestigial structure See *vestigial*.

vibrio A spirillum (spiral-shaped bacterium) that is shaped like a comma. Compare with *spirillum*, *spirochete*, *bacillus*, and *coccus*.

villus (pl., *villi*) A multicellular, minute, elongated projection from the surface of an epithelial membrane (e.g., villi of the mucosa of the small intestine).

virion A complete virus particle that is outside a cell.

viroid (vy'-roid) A tiny, naked, infectious particle consisting only of nucleic acid.

virulence Properties that render an infectious agent pathogenic (and often lethal) to its host. Compare with *avirulence*.

virus A tiny pathogen consisting of a core of nucleic acid usually encased in protein and capable of infecting living cells; a virus is characterized by total dependence on a living host.

viscera (vis'-ur-uh) The internal body organs, especially those located in the abdominal or thoracic cavities.

visceral mass The concentration of body organs (viscera) located above the foot in mollusks.

vital capacity The maximum volume of air a person exhales after filling the lungs to the maximum extent.

vitamin A complex organic molecule required in very small amounts for normal metabolic functioning.

vitelline envelope An acellular covering of the eggs of certain animals (e.g., echinoderms), located just outside the plasma membrane.

viviparous (vih-vip'-er-us) Bearing living young that develop within the body of the mother. Compare with *oviparous* and *ovoviviparous*.

voltage-activated ion channels Ion channels in the plasma membrane of neurons that are regulated by changes in voltage. Also called *voltage-gated channels*.

vomer nasal organ In mammals, an organ in the epithelium of the nose, made up of specialized chemoreceptor cells that detect pheromones.

vulva The external genital structures of female mammals.

warning coloration See *aposematic coloration*.

water mold A funguslike stramenopile protist with a body consisting of a coenocytic mycelium that reproduces asexually by forming motile zoospores and sexually by forming oospores.

water potential Free energy of water; the water potential of pure water is zero and that of solutions is a negative value. Differences in water potential are used to predict the direction of water movement (always from a region of less negative water potential to a region of more negative water potential).

watershed Area of land where all the water that drains off of it (runoff) goes into the same body of water.

water vascular system Unique hydraulic system of echinoderms; functions in locomotion and feeding.

wavelength The distance from one wave peak to the next; the energy of electromagnetic radiation is inversely proportional to its wavelength.

weathering processes Chemical or physical processes that help form soil from rock; during weathering processes, the rock is gradually broken into smaller and smaller pieces.

Wernicke's area Located in the left temporal lobe; center for language and comprehension.

Western blot A technique in which proteins, previously separated by gel electrophoresis, are transferred to paper. A specific labeled antibody is generally used to mark the location of a particular protein. Compare with *Southern blot* and *Northern blot*.

whisk ferns Fern relatives lacking true roots and leaves; characterized by dichotomous branching.

white blood cells (WBC) See *leukocytes*.

white matter Nervous tissue in the brain and spinal cord that contains myelinated axons. Compare with *gray matter*.

wild type The phenotypically normal (naturally occurring) form of a gene or organism.

winds Complex horizontal atmospheric movements caused in part by differences in atmospheric temperature and pressure changes, Earth's rotation, and uneven heating of the oceans and continents.

wobble hypothesis Describes the ability of some tRNA anticodons to associate with more than one mRNA codon; in these cases the 5' base of the anticodon is capable of forming hydrogen bonds with more than one kind of base in the 3' position of the codon.

work Any change in the state or motion of matter.

X chromosome One of the two sex chromosomes of mammals and some other organisms; normal human females are XX, normal males are XY. Compare with *Y chromosome*.

X-linked gene A gene carried on an X chromosome.

X-ray diffraction A technique for determining the spatial arrangement of the components of a crystal.

xylem (zy'-lem) The vascular tissue that conducts water and dissolved minerals in plants.

XXX karyotype Chromosome constitution that causes affected individuals (who are fertile males) to be unusually tall, with severe acne.

Y chromosome One of the two sex chromosomes of mammals and some other organisms; the Y chromosome determines male gender in humans; normal females are XX, normal males are XY. Compare with *X chromosome*.

yeast A unicellular fungus (usually an ascomycete) that reproduces asexually by budding or fission, and sexually by ascospores.

yolk In many animal eggs, a mixture of nutrients (mostly proteins and lipids) that nourish the developing embryo.

yolk sac One of the extraembryonic membranes; a pouchlike outgrowth of the digestive tract of embryos of certain vertebrates (e.g., birds) that grows around the yolk and digests it. Embryonic blood cells are formed in the mammalian yolk sac, which lacks yolk.

zero population growth Point at which the birth rate equals the death rate. A population with zero population growth does not change in size.

zona pellucida (pel-loo'-sih-duh) The thick, transparent covering that surrounds the plasma membrane of a mammalian ovum.

zoonotic disease An animal disease that crosses the species barrier and infects humans.

zooplankton (zoh'-oh-plank'-tun) The nonphotosynthetic organisms present in plankton (e.g., protozoa, tiny crustaceans) and the larval stages of many animals. See *plankton*. Compare with *phytoplankton*.

zoosporangium Structure in which zoospores form.

zoospore (zoh'-oh-spore) A flagellated motile spore produced asexually by chytrids, certain algae, water molds, and other protists.

zooxanthellae (zoh'-oh-zan-thel'-ee) (sing., *zooxanthella*) Endosymbiotic, photosynthetic dinoflagellates found in certain marine invertebrates; their mutualistic relationship with corals enhances the corals' reef-building ability.

zygomycetes (zy'-gah-my'-seats) Fungi characterized by the production of nonmotile asexual spores and sexual zygospores.

zygosporangium (zy'-gah-spor-an'-gee-um) A thick-walled sporangium containing a zygospore.

zygospore (zy'-gah-spor) A sexual spore produced by a zygomycete.

zygote The $2n$ cell that results from the union of n gametes in sexual reproduction. Species that are not polyploid have haploid gametes and diploid zygotes.

zygotonic genes Genes that are transcribed after fertilization, either in the zygote or in the embryo. Compare with *maternal effect genes*.

The letter *i* designates illustrations;
t designates tables; **bold** designates
defined or introduced term.

Scientific Measurement

Some Common Prefixes		
		Examples
kilo	1000	a kilogram is 1000 grams
centi	0.01	a centimeter is 0.01 meter
milli	0.001	a milliliter is 0.001 liter
micro (μ)	one-millionth	a micrometer is 10^{-6} (one-millionth) of a meter
nano (n)	one-billionth	a nanogram is 10^{-9} (one-billionth) of a gram
pico (p)	one-trillionth	a picogram is 10^{-12} (one-trillionth) of a gram

The relationship between mass and volume of water (at 20°C):
 $1\text{ g} = 1\text{ cm}^3 = 1\text{ mL}$

Some Common Units of Length		
Unit	Abbreviation	Equivalent
meter	m	approximately 39 in.
centimeter	cm	10^{-2} m
millimeter	mm	10^{-3} m
micrometer	μm	10^{-6} m
nanometer	nm	10^{-9} m

Length Conversions		
1 in. = 2.5 cm	1 mm = 0.039 in.	
1 ft = 30.48 cm	1 cm = 0.39 in.	
1 yd = 0.9 m	1 m = 39 in.	
1 mi = 1.6 km	1 m = 1.094 yd	
	1 km = 0.6 mi	

To convert	Multiply by	To obtain
inches	2.54	centimeters
feet	30.48	centimeters
centimeters	0.39	inches
millimeters	0.039	inches

Standard Metric Units		
		Abbreviation
Standard unit of mass	gram	g
Standard unit of length	meter	m
Standard unit of volume	liter	L

Some Common Units of Volume

Unit	Abbreviation	Equivalent
liter	L	approximately 1.06 quarts
milliliter	mL	10^{-3} L (1 mL = 1 cm ³ = 1 cc)
microliter	μ L	10^{-6} L

Volume Conversions

1 tsp = 5 mL	1 mL = 0.03 fluid ounce
1 tbs = 15 mL	1 L = 2.1 pints
1 fl oz = 30 mL	1 L = 1.06 quarts
1 cup = 0.24 L	1 L = 0.26 gallon
1 pt = 0.47 L	
1 qt = 0.95 L	
1 gal = 3.79 L	

To convert	Multiply by	To obtain
fluid ounces	30	milliliters
quart	0.95	liters
milliliters	0.03	fluid ounces
liters	1.06	quarts

Energy Conversions

calorie (cal) = energy required to raise the temperature of 1 g of water (at 16°C) by 1°C

1 calorie = 4.184 joules

1 kilocalorie (kcal) = 1000 cal

1 joule = 0.24 cal

1 kilocalorie = 4.184 kJ

Temperature Scales

Temperature Conversions

Celsius (Centigrade) = °C

$$^{\circ}\text{C} = \frac{(^{\circ}\text{F} - 32) \times 5}{9}$$

Fahrenheit = °F

$$^{\circ}\text{F} = \frac{^{\circ}\text{C} \times 9}{5} + 32$$

Kelvin = K

K = °C + 273

Some Common Units of Mass

Unit	Abbreviation	Equivalent
kilogram	kg	10^3 g (approximately 2.2 lb)
gram	g	approximately 0.035 oz
milligram	mg	10^{-3} g
microgram	μ g	10^{-6} g
nanogram	ng	10^{-9} g
picogram	pg	10^{-12} g

Mass Conversions

1 oz = 28.3 g

1 lb = 453.6 g

1 lb = 0.45 kg

To convert	Multiply by	To obtain
ounces	28.3	grams
pounds	453.6	grams
pounds	0.45	kilograms
grams	0.035	ounces
kilograms	2.2	pounds

atomic mass unit (amu) or Dalton — the approximate mass of a proton or neutron

mole — the formula weight of a substance expressed in grams

Avogadro's number (N) = 6.02×10^{23} — the number of particles in one mole of any substance
